Viral encephalitis has an estimated incidence of 7 per 100,000 per year. In general, a specific cause is identified in only 10 to 20% of patients in the United States. Many viruses (Table 422-1) are implicated, and testing by serologic or nucleic acid identification (by polymerase chain reaction [PCR]) is required to identify the specific virus. The epidemiology of each virus responsible for central nervous system infection is unique in terms of the types of patients who are at highest risk, geographic distribution, and seasonal occurrence, especially the arboviruses (Chapter 391) and enteroviruses (Chapter 387), which are covered in separate chapters.

In the United States, the most common cause of nonepidemic encephalitis is herpes simplex encephalitis, which is caused by herpes simplex virus type 1 (Chapter 382). The most common epidemic virus in the United States is now West Nile virus (Chapter 391), which is a Flavivirus related to St. Louis encephalitis virus and to its Asian counterpart Japanese encephalitis virus. There is serologic cross-reactivity between St. Louis encephalitis, Japanese encephalitis, and West Nile viruses.

PATHOBIOLOGY

In general, gross pathologic inspection of an encephalitic brain does not reveal purulence visible to the naked eye. If focal purulence is present, *cerebritis* is the more correct term. If frank necrosis and purulence are present, the correct pathologic term is *brain abscess* (Chapter 421). Encephalitis, however, can be associated with substantial necrosis, and patients with severe acute viral encephalitis frequently have microscopic evidence of necrosis. Certain viral encephalitides, such as herpes simplex encephalitis, can be frankly hemorrhagic. Viruses that cause acute encephalitis may often also cause meningitis (Chapter 420). Indeed, patients with encephalitis virtually always have some microscopic inflammatory changes in the leptomeninges. Conversely, patients with viral meningitis will inevitably have some component of microscopic encephalitis. The degree of inflammatory change present in the brain is determined by the individual viral pathogen and by host immune factors, which are responsible for the reaction to the invading virus.

CLINICAL MANIFESTATIONS

The clinical findings in patients with acute viral encephalitis start with a prodrome of fever, malaise, myalgia, and nonspecific symptoms. Nausea, vomiting, diarrhea, cough, sore throat, and rash can precede the neurologic symptoms. Invasion of the nervous system is typically accompanied by headache, photophobia, and altered consciousness, with symptoms progressing over a period of several days. Seizures are also a common heralding symptom. Meningeal signs are variably present and are an unreliable finding in encephalitis.

Focal brain dysfunction is seen with some viruses. For example, West Nile virus (Chapter 391) can cause a brain stem encephalitis with an early onset of coma. Herpes simplex virus (Chapter 382) tends to cause focal cortical neurologic deficits, including hemiparesis, aphasia, and seizures. Limbic system involvement in herpes simplex encephalitis or rabies can lead to prominent behavioral changes at the beginning of the illness before the patient's level of consciousness is depressed. Focal or generalized seizures, which suggest cortical involvement, are particularly common when herpes simplex encephalitis affects the hippocampus and limbic system. Rabies is typically associated with laryngospasm, hydrophobia, and depressed consciousness. Because of spinal cord involvement, West Nile virus, St. Louis encephalitis virus, poliovirus, and rabies virus infections can cause focal or asymmetrical weakness of the lower motor neuron type with areflexia.

DIAGNOSIS

In patients with coma or focal deficits, computed tomography (CT) of the head is typically performed before spinal fluid analysis to exclude a substantial mass effect and to avoid the risk for herniation during lumbar puncture. In patients without focal findings, however, lumbar puncture should be performed immediately to establish the diagnosis and allow early treatment. Opening pressures should be measured because increased intracranial pressure can occur with all forms of viral encephalitis.

Spinal fluid analysis, essential in suspected cases of viral encephalitis, typically reveals an elevated protein level, which usually is less than 120 mg/dL. The cerebrospinal fluid (CSF) glucose level is typically normal and greater than 40% of the coincident serum value, but some patients may rarely have a low CSF glucose level suggestive of a bacterial infection (Chapter 420). The white blood cell count is typically elevated, usually in the range of 10 to 500 cells/mm^3 and generally with a lymphocytic predominance. However, a polymorphonuclear predominance is seen in some cases of West Nile encephalitis and cytomegalovirus ventriculitis.

Serologic or PCR testing on spinal fluid is frequently helpful (Table 422-2). PCR testing has the added advantage of proving direct viral infection within the central nervous system, but serologic testing is more appropriate for West Nile virus encephalitis, which is best confirmed by an IgM antibody response in spinal fluid.

Magnetic resonance imaging (MRI) of the brain is the most sensitive technique for defining abnormalities in patients with viral encephalitis. However, frank viral encephalitis can occur with normal findings on MRI. The specific patterns can suggest the virus responsible; the best example is herpes simplex encephalitis, which has a characteristic pattern involving the mesiotemporal, inferofrontal, and insular cortices, usually unilateral or asymmetrically bilateral.

Differential Diagnosis

A number of nonviral pathogens can cause encephalitis that is clinically and pathologically indistinguishable from viral encephalitis. Examples include *Rickettsia* (Chapter 335), *Borrelia* (Chapter 329), Whipple's disease (Chapter 142), *Toxoplasma* (Chapter 357), and *Acanthamoeba* (Chapter 360). Additionally, autoimmune encephalitides that mimic viral encephalitis include limbic paraneoplastic encephalitis, Hashimoto's encephalopathy associated with autoimmune thyroiditis (Chapter 233), and encephalitis associated with anti–*N*-methyl-D-aspartate (NMDA) receptor antibodies. In parainfectious encephalitis, a systemic viral infection is associated with a febrile encephalopathy, sometimes with inflammatory spinal fluid but without direct evidence of brain invasion by the organism. Examples of parainfectious encephalitis include infection and encephalopathy associated with influenza virus (Chapter 372), varicella virus (Chapter 383), and Epstein-Barr virus (Chapter 385). Furthermore, manifestations of parainfectious effects by viruses may include severe brain white matter inflammation or demyelination referred to as acute disseminated encephalomyelitis.

TABLE 422-2 SELECTED TESTS FOR VIRAL ENCEPHALITIS

ORGANISM/ SYNDROME	TEST	COMMENT
WEST NILE VIRUS		
West Nile encephalitis	IgM in CSF	Diagnostic of CNS invasive disease or acute flaccid paralysis
HERPES SIMPLEX VIRUS TYPE 1		
Herpes simplex encephalitis	PCR in CSF	Sensitive and specific in the acute phase
	CSF–serum antibody ratio	Useful 2 weeks to 3 months after onset
HERPES SIMPLEX VIRUS TYPE 2		
Neonatal encephalitis	PCR in CSF	Confirmatory, high sensitivity
Relapsing meningitis	PCR in CSF	Sensitive and specific in first 3 days of illness
VARICELLA-ZOSTER VIRUS		
Meningoencephalitis	PCR in CSF	Confirmatory when used with clinical and spinal fluid findings; sensitivity unclear
EPSTEIN-BARR VIRUS		
EBV encephalitis	PCR in CSF	Suggests CNS invasion by virus
JC VIRUS		
Progressive multifocal leukoencephalopathy	PCR in CSF	Diagnostic but incompletely (70%) sensitive
CYTOMEGALOVIRUS		
CMV ventriculitis	PCR in CSF	Sensitive and specific

CNS = central nervous system; CSF = cerebrospinal fluid; PCR = polymerase chain reaction.

SELECTED SPECIFIC VIRUSES

Herpes Simplex Encephalitis

EPIDEMIOLOGY

Herpes simplex (Chapter 382) encephalitis, which is second only to West Nile encephalitis as the most common form of nonepidemic encephalitis in the United States, has an annual incidence of two to four cases per million people per year. There is no seasonal or gender predisposition. The encephalitis can strike older children as well as adults, although it is most commonly a disease of adults.

PATHOBIOLOGY

Herpes simplex encephalitis can occur in immunosuppressed or immunocompetent patients. Patients who are deficient in toll-like receptor 3 in the immune system may be selectively vulnerable to herpes simplex encephalitis.

Herpes simplex virus type 1 infects and establishes latency in the majority of the population. Whether herpes simplex encephalitis arises from reactivation of a latent viral infection in the trigeminal ganglion or is a primary nasopharyngeal infection that ascends into the olfactory nervous system is uncertain.

The pathology of herpes simplex encephalitis is a necrotizing, hemorrhagic, inflammatory encephalitis in the mesiotemporal, inferofrontal, and insular cortices, with gray matter being affected more than white matter. When the brain is affected bilaterally, the pathologic features are usually asymmetrical, a pattern that helps distinguish herpes simplex from other forms of limbic encephalitis.

CLINICAL MANIFESTATIONS

The clinical manifestations of herpes simplex encephalitis usually begin with a nonspecific febrile prodrome, which is followed within hours to days by the symptoms of headache, malaise, nausea, and vomiting. A reduced level of consciousness may occur early. Seizures may be the first manifestation of this encephalitis. Focal deficits, especially hemiparesis or aphasia, are common. More specific manifestations of herpes simplex encephalitis are symptoms of limbic system–associated behavioral changes, such as behavioral or emotional lability and inappropriateness. Memory is affected early if consciousness is preserved. As the encephalitis progresses, symptoms of increased

intracranial pressure, lethargy, and coma are usual. Focal findings alone in the context of encephalitis are not sufficient to confirm a diagnosis of herpes simplex encephalitis.

DIAGNOSIS

Spinal fluid analysis is a mainstay in the diagnosis of herpes simplex encephalitis. In a patient with focal encephalitis or coma, however, CT of the brain should be performed before spinal fluid analysis to avoid the risk for herniation. Elevation of the protein level and the white blood cell count, with a predominance of lymphocytes, is the most frequent pattern; red blood cells are also commonly seen. The CSF glucose level is usually normal, but it can be less than 50% of the blood glucose level in about 5% of patients.

The best and most accurate test for proof of herpes simplex encephalitis is the presence of herpes simplex virus type 1 DNA amplified by PCR in the spinal fluid. Herpes simplex virus type 1 can be distinguished from herpes simplex virus type 2 by specific primer amplification, applied as part of the PCR analysis. Because herpes simplex type 2 can cause encephalitis in neonates and meningitis in adults, this distinction may affect therapy.

MRI, which is the imaging technique of choice for this form of suspected encephalitis, typically shows characteristic focal involvement with increased T2 and fluid-attenuated inversion recovery (FLAIR) signal in the mesiotemporal lobes (including the amygdala, hippocampus, and uncus), the inferofrontal lobes (cingulate gyrus and orbital frontal cortex), and the insular cortex. The abnormalities seen on MRI are often unilateral but can be bilateral and asymmetrical. Focal MRI abnormalities must be distinguished from brain abscess (Chapter 421), cerebral infarction (Chapter 414), cerebral hemorrhage (Chapter 415), brain tumors (Chapter 195), and paraneoplastic limbic encephalitis(Chapter 197); radiographically detected involvement of the mesiotemporal rather than the lateral temporal areas and involvement of the gray matter rather than the white matter suggest herpes simplex encephalitis as the diagnosis. Early gadolinium contrast enhancement may occur but is not universal.

CT of the head is less sensitive than MRI for detecting mild cases of herpes encephalitis. However, because herpes simplex encephalitis can be hemorrhagic, CT may sometimes identify the hemorrhage more accurately than MRI can.

Electroencephalography is an adjunctive test that can show periodic lateralized epileptiform discharges ipsilateral to the involved temporal lobe. However, the findings are not specific for herpes simplex encephalitis and commonly occur in patients with cerebral infarction (Chapter 414) and occasionally other forms of viral encephalitis.

TREATMENT Rx

Multicenter prospective trials emphasize that early treatment affects outcome. When suspicion for herpes simplex encephalitis is raised in the acute setting by the presence of focal signs or symptoms, early empirical treatment is recommended even while the diagnostic evaluation is proceeding.

Intravenous acyclovir (30 mg/kg daily given three times per day in divided doses for 14 to 21 days) is the therapy of choice.■ Some experts have suggested treatment using the same doses for 21 days, but no prospective data show that a longer duration of therapy or higher doses of acyclovir affect neurologic outcomes.

Rabies

Human rabies, which is an encephalitic illness caused by the rabies virus, is usually transmitted by an animal bite. It produces a fatal encephalitis, although the latency between animal bite exposure and occurrence of neurologic symptoms may make the diagnosis unsuspected.

EPIDEMIOLOGY AND PATHOBIOLOGY

Rabies is a rare illness in the United States and developed world. However, initially unsuspected cases have been transmitted via trivial bites by infected bats, which are widely distributed in every state in the United States except Hawaii. Rabies virus variants in bats are now responsible for the majority of recent human cases in the United States and Canada. Raccoon rabies has extended from Florida into Georgia, Alabama, and South Carolina.

Canine rabies is still endemic in much of the developing world, including Africa, Latin America, Eastern Europe, and Asia, and the vast majority of human rabies cases occur as a result of untreated dog bites from endemic areas. Dog rabies came under control in the United States during the 1950s and was associated with a marked reduction in the number of human cases transmitted by dogs. Much of the dog-related clinical rabies seen in the United States is the result of dog bites that occurred in developing countries, before the patient migrated to the United States. Rare cases of transmission of rabies to transplant organ recipients have occurred recently in the United States.

The presence of Negri bodies (intracytoplasmic viral inclusions) in neurons of the brain stem, cerebellum (especially the Purkinje cells), or hippocampus defines rabies pathologically. These inclusions are often not present, but detection of antigen by immunohistochemical means can aid in the pathologic diagnosis. Because the disorder tends to be a brain stem encephalitis, the cardiovascular, bulbar, and respiratory centers are affected.

CLINICAL MANIFESTATIONS

Clinically, human rabies usually develops 20 to 90 days after a bite, although rarely disease develops after only a few days or after a year or more following bite exposure. Multiple bites and facial bites are associated with shorter incubation times.

Nonspecific prodromal symptoms include fever, chills, malaise, fatigue, insomnia, anorexia, headache, and irritability. In the majority of patients, pain or paresthesias will develop in the limb that was affected by the bite. Following the prodromal illness, an encephalitic form develops in about 80% of patients and causes varied behavior from episodes of agitated arousal to quiet lethargy. Fever is a common accompaniment but not universal at this phase. Disinhibition of brain stem reflexes leads to hydrophobia with laryngospasm and an inability to deal with salivation, swallowing of water, or other oral intake. When the brain stem encephalitis affects the bulbar, cardiovascular, and respiratory centers, autonomic dysfunction, cardiopulmonary complications, and respiratory failure may occur.

Another form of rabies that affects up to a third of patients is known as paralytic rabies. This form of rabies is manifested as acute flaccid paralysis, which may be multifocal and affect the limbs, as well as the bulbar musculature. The weakness can mimic poliomyelitis (Chapter 423) because of its multifocality, and it can be confused with Guillain-Barré syndrome (Chapter 428). Paralytic rabies typically occurs in conjunction with encephalitis.

DIAGNOSIS

Findings on spinal fluid analysis may be abnormal in human rabies. A pleocytosis, usually less than 100 white cells/μL, is found in more than 50% of patients in the first week of illness; the leukocytes are predominantly mononuclear. The protein concentration is commonly mildly elevated, and the glucose level is usually normal.

Imaging of patients with rabies is sometimes useful. MRI may show gray matter involvement and involvement of the brain stem in particular, with increased T2 signal, commonly without enhancement. Spinal cord MRI in patients with paralytic rabies may show increased T2 signal mimicking acute disseminated encephalomyelitis. Involvement of brain gray matter, including the hippocampus and basal ganglia structures, indicates the gray matter predilection and often bilateral involvement of supratentorial structures. However, imaging cannot be relied on to exclude rabies.

Serum antibodies against rabies virus are not usually present in unimmunized patients until the second week of illness, and patients can die before having a detectable serum antibody level. Serum antibodies may also be present in spinal fluid, but their absence is unreliable in excluding the diagnosis. Classically, staining a skin biopsy sample taken from an area near the nape of the neck for rabies antigen in the sensory nerves can confirm the diagnosis of rabies. Alternatively, small amounts of rabies RNA can be detected by PCR testing. Typical specimens to detect virus include saliva, brain tissue, or spinal fluid. A positive result confirms the diagnosis, but the exclusionary value of negative results is unknown.

TREATMENT Rx

After an animal bite, local treatment with antirabies immunoglobulin and systemic treatment with vaccination are typically offered. Rabies postexposure prophylaxis includes local wound cleansing, passive immunization with immunoglobulin, and active immunization with rabies vaccine. Inactivated cell culture rabies vaccines are used for active immunization, and the risk for vaccination-induced acute disseminated encephalomyelitis has been markedly reduced by the use of these vaccines. However, once rabies encephalitis is manifested, it is unclear whether vaccination, though regularly used, has any

role in improving outcome. Antiviral therapy and a variety of immunotherapies, including ribavirin and interferon alfa, have been tried in the treatment of rabies, usually without success. Although one patient was reputed to survive with the use of therapeutic coma without vaccination, subsequent reports of patients treated in similar fashion have been associated with a fatal outcome.

Rare Causes of Encephalitis

Lymphocytic choriomeningitis (Chapter 420) virus is a human infection acquired from mice. Typically, humans acquire the infection by contact with food or dust that is contaminated by excreta of the common house mouse. Most commonly, human disease occurs in winter, when the natural host tends to move indoors. It can also be acquired as a consequence of laboratory exposure by human caretakers.

Mumps virus (Chapter 377) is typically acquired by the respiratory route. Infection can occur throughout the year, but the incidence is higher during the spring. Although mumps virus infects both sexes equally, meningoencephalitis develops in males three times more frequently than in females. Vaccination programs in the United States have made mumps encephalitis rare.

TREATMENT

Rx

Effective antiviral therapy does not exist for viral encephalitis, except for herpes simplex encephalitis. However, because of the usual delay in establishing or excluding the diagnosis of herpes simplex encephalitis, patients suspected of having encephalitis should start acyclovir therapy (10 mg/kg intravenously every 8 hours for 2 weeks) even while specific serologic and spinal fluid analyses are being performed to make a specific diagnosis.

Supportive measures for patients with encephalitis typically include intensive care unit monitoring and treatment in the initial phases of the illness. Seizures are common and frequently refractory to antiepileptic drugs; however, the seizures themselves can increase morbidity and mortality, so vigorous treatment attempts are required (Chapter 410).

In patients who are immunosuppressed (see Table 422-1), the spectrum of possible infections is broader and potentially more treatable. Examples include varicella-zoster virus (Chapter 383), with acyclovir administered at doses similar to those used for herpes simplex virus, and cytomegalovirus (Chapter 384), with ganciclovir administered at 5 mg/kg intravenously every 12 hours for 2 weeks or cidofovir administered at 5 mg/kg intravenously weekly for 2 weeks, although some patients require long-term oral valganciclovir (900 mg every 24 hours) or intravenous cidofovir (5 mg/kg every 2 weeks). By comparison, no specific treatments are currently effective for Epstein-Barr virus (Chapter 385) and JC virus (progressive multifocal leukoencephalopathy, Chapter 378).

PROGNOSIS

The prognosis of encephalitis is dependent on the cause. Herpes simplex encephalitis, even with adequate treatment, has a 20% mortality, and the likelihood of major persistent morbidity with seizures or defects in memory and behavior is 35 to 40%. Each of the arboviruses has a different mortality rate, with eastern equine encephalitis virus associated with the highest mortality. LaCrosse encephalitis virus has the lowest mortality and is the most benign. Some forms of encephalitis have specific sequelae, such as sensorineural deafness or hydrocephalus associated with mumps encephalitis.

POLIOMYELITIS

ALLEN J. AKSAMIT, JR.

DEFINITION

Poliomyelitis is an acute viral illness that is associated with encephalitic features and acute flaccid paralysis. Enterovirus 71 (Chapter 387) and West Nile virus (Chapter 391) can cause an identical clinical illness.

EPIDEMIOLOGY

The cause of poliomyelitis is the poliovirus, which is serotyped into three subtypes (types 1, 2, and 3) and belongs to the group of enteroviruses in the family Picornaviridae. Most clinical disease is caused by the type 1 strain. Vaccination eliminated polio epidemics in the United States and Europe in the 1960s. The last major polio epidemic in the United States occurred in 1960, with a steady decline in cases subsequently. The last case of wild-virus poliomyelitis in the United States was reported in 1979. However, polio continues to remain a significant illness in unvaccinated areas of the world, particularly in Nigeria, Pakistan, and Afghanistan. In temperate climates, poliovirus infections occur most often in the summer and fall months, but infection occurs throughout the year in tropical areas.

Because of its oral-fecal, host-to-host transmission, poliovirus infection is influenced by standards of hygiene. The greatest risk for transmission occurs in family members and other direct contacts, especially under crowded conditions. The incubation period is about 3 to 6 days, after which virus may be shed into the nasopharynx for 2 to 6 weeks and into feces for several months.

Although poliovirus infects many exposed individuals, the acute flaccid paralysis of poliomyelitis occurs in only 1 to 2% of infected persons. The precise factors that cause dissemination of virus to the nervous system and susceptibility to paralytic disease are unknown. Paralytic disease occurs more commonly in children and young adults.

Historically, in the United States, poliomyelitis occasionally resulted from the live attenuated poliovirus vaccine. The risk for *vaccine-associated poliomyelitis* was about 1 case in 2.4 million doses, with most of the risk occurring with the first dose. About 75% of cases were related to immunocompetent vaccine recipients; about half of these cases occurred in the vaccinated person, most of the remainder occurred in healthy close contacts of vaccine recipients, but about 5% occurred in healthy community contacts who had not been vaccinated recently and had not been in direct contact with vaccine recipients. The remaining 25% or so cases occurred in immunocompromised persons, in whom clinical disease is about 5000-fold more likely to develop than in immunocompetent persons, or in the direct contacts of immunocompromised persons. The live attenuated virus in the vaccine can also mutate to cause *vaccine-derived poliomyelitis*, which can infect unvaccinated persons and lead to clinical polio with an attack rate and severity similar to that of wild-type virus. The inactivated polio vaccine, which is the only vaccine currently in use in the United States since the year 2000, does not cause vaccine-induced polio.

PATHOBIOLOGY

Polioviruses are small (approximately 27 nm), roughly spherical particles with a single-stranded RNA core surrounded by a protein capsid. Poliovirus is an enterovirus that is ingested orally and replicates initially in the lymphatic system of the gastrointestinal tract, especially in Peyer's patches in the small intestine. Spread to the local gastrointestinal lymphatics is followed by systemic viremia, which seeds the nervous system, although the precise mechanism of entry into the nervous system is not well established. The virus can replicate in skeletal muscle, where it may cause the myalgias that often precede weakness. One hypothesis is that the virus is then spread via peripheral motor axons to the spinal cord by retrograde transport, where it selectively replicates in the anterior horn cells. Pathology indicates a disseminated asymmetrical pattern of infection of the anterior horn cells of the spinal cord. Death of anterior horn cells leads to permanent paralysis, but compensation by collateral sprouting from uninfected cells in the same segment of the cord can allow some improvement in functional status and motor recovery.

CLINICAL MANIFESTATIONS

Acute poliomyelitis has two phases. An initial phase coincides with viremia and is associated with fever and headache and sometimes with sore throat; it resolves in 1 to 4 days. The second phase of illness, which usually occurs 7 to 21 days (range, 4 to 30 days) after the initial infection, is associated with abrupt fever, headache, vomiting, and meningismus, presumably as a result of viral infection in the central nervous system. The meningitic symptoms of headache and stiff neck subsequently resolve but are rapidly followed by asymmetrical, multifocal muscle weakness of the lower motor neuron type, sometimes with severe myalgias.

Clinical examination shows weakness affecting muscles in an asymmetrical and multifocal fashion, with a corresponding reduction in muscle stretch reflexes. Sensation is normal, thereby attesting to the selective involvement of the anterior horns of the spinal cord. Neurogenic muscular atrophy rapidly follows in affected muscles. The extent of motor involvement is typically completed within 1 week.

The upper and lower limb, truncal, and respiratory muscles are affected. Muscles innervated by the bulbar (medullary) cranial nerves (9^{th}, 10^{th}, 11^{th}, or 12^{th}) are often involved. The facial nerve can be involved, but the eye muscles are usually spared. Rarely, direct involvement of the brain stem reticular formation can cause an encephalitic illness with coma or cause death by its effects on breathing and cardiovascular control.

DIAGNOSIS

In addition to the typical symptoms and signs, the diagnosis of poliomyelitis is aided by analysis of spinal fluid. Spinal fluid typically shows a pleocytosis with lymphocytic predominance. The spinal fluid protein level is elevated, but the glucose level is normal. Enteroviruses may be cultured from the spinal fluid, but specific viral studies identifying poliovirus and other enteroviruses are best accomplished by polymerase chain reaction (PCR) testing. More specific characterization of the individual virus type can be accomplished by direct sequencing of the genome.

Differential Diagnosis

Other viral causes of encephalomyelitis can mimic poliomyelitis. Enterovirus 71 (Chapter 387) can cause epidemics of fever and acute flaccid paralysis. Coxsackievirus 7 and enterovirus 70 can cause milder paralytic syndromes, usually without fever. West Nile virus (Chapter 391) infection of the central nervous system is also associated with fever and acute flaccid paralysis. Tick-borne encephalitis virus (Chapter 391), native to Russia, may behave similarly. A paralytic form of rabies encephalitis (Chapter 422) can lead to asymmetrical acute flaccid paralysis. Serologic and virologic testing can distinguish these other agents. Testing for West Nile virus detects IgM antibodies against the virus in spinal fluid. Rabies may be tested for by either serology or PCR testing for the rabies virus (Chapter 422).

Ascending or descending paralysis can also be seen in a variety of non-infectious or postinfectious illnesses, such as Guillain-Barré syndrome (Chapter 428) and acute inflammatory myelopathy (Chapter 407). Diphtheria (Chapter 300) can be associated with focal paralytic syndromes.

PREVENTION

Poliomyelitis can be prevented by lifelong immunity induced by either the live attenuated (oral) or killed (inactivated) polio vaccines, which are routinely given to children. Oral polio vaccine is relatively inexpensive, about $0.08 per dose. Short-term shedding of vaccine virus in the stools of recently immunized children leads to passive immunization of close contacts, thereby providing the ability of mass campaigns to interrupt the transmission of wild poliovirus. However, about 1 in every 2.5 million doses of the vaccine can cause *vaccine-associated* poliomyelitis with paralysis in the vaccinated child, in a close contact, or even in another person. Rarely, a strain of poliovirus in the oral polio vaccine may change genetically and circulate to cause *vaccine-derived* poliomyelitis. In endemic countries, this low risk for vaccine-associated polio and vaccine-derived polio is preferable to the much higher risk for polio from wild-type virus without vaccination.

In countries where the risk of disease from wild-type poliovirus is zero, however, programs have shifted to using inactivated polio vaccine. Inactivated polio vaccine, which is about five times as expensive as oral vaccine, produces protective antibodies that prevent the poliovirus from spreading from the intestinal tract to the central nervous system. Unlike oral polio vaccine, it does not prevent the spread of wild poliovirus and cannot contain an epidemic because virus can still multiply inside the intestines and be shed in stool.

In the United States, debate about the efficacy and risks of live attenuated versus killed vaccine ended in 2000 with a policy that exclusively uses the inactivated polio vaccine, which does not lead to vaccine-associated or vaccine-derived polio. Global eradication strategies using live attenuated vaccine now focus especially on Nigeria, India, Afghanistan, and Pakistan, where polio remains endemic.

TREATMENT AND PROGNOSIS

Rx

No specific treatment is available for patients affected by poliomyelitis caused by poliovirus. However, supportive therapy, including intensive care treatment to maintain respiratory function and provide cardiovascular support, can stabilize the patient and allow rehabilitation.

Death in patients with poliomyelitis is usually the result of bulbar muscle, respiratory, and cardiovascular impairment. With intensive treatment of respiratory insufficiency, patients can survive the acute paralytic illness. In general, motor improvement begins within a month after the onset of illness. On follow-up, many patients are left with profound neurologic deficits; others may return fully to activities of daily living, but some neurologic residua can usually be found on clinical or electrophysiologic examination.

Postpolio Syndromes

In patients who have had paralytic poliomyelitis, progressive atrophy and weakness can develop after more than 10 to 15 years of stable neurologic function. This syndrome, which is known as postpolio progressive muscular atrophy, is postulated to result from the normal age-related loss of motor neurons from a motor neuron pool already depleted by the viral illness. A second symptom complex in survivors of paralytic polio is characterized by progressive muscle pain, weakness, and fatigue; this "postpolio syndrome," which may affect up to 60% of patients infected during a polio epidemic, is not related to persistent viral infection and is of unknown cause.

PRION DISEASES

PATRICK J. BOSQUE

DEFINITION

Prion diseases, which are a group of closely related neurodegenerative conditions of humans and other mammals, are caused by an accumulation of aggregated forms of the prion protein (PrP) in the central nervous system (CNS). These conditions can be transmitted by an infectious agent, the prion, that is composed of misfolded and aggregated PrP. The prion contains no specific nucleic acid. The name Creutzfeldt-Jakob disease (CJD) is applied to most human forms of prion disease, although other names are used for some forms.

EPIDEMIOLOGY

Prion diseases occur worldwide, with an incidence of about one case per million annually in most populations. These conditions can be acquired sporadically, genetically, or infectiously. Sporadic disease accounts for about 90% of cases, and genetic forms account for almost all the remainder. Cases acquired by infection are exceedingly rare in humans and account for less

than 1% of cases in most populations. Both dietary and iatrogenic exposure has transmitted prion disease to humans.

Kuru, the first human prion disease recognized to be transmissible, was caused by ceremonial cannibalism in tribes of the Fore language group in the highlands of New Guinea. The last episodes of exposure are thought to have occurred in the late 1950s, but the few cases that have occurred in the past decade indicate an incubation period that approaches 50 years.

Variant CJD is caused by exposure, presumably by the alimentary route, to prions from cattle with bovine spongiform encephalopathy. It first arose in Great Britain in 1994, about 10 years after the first cases of bovine spongiform encephalopathy there. Despite the exposure of millions of people to meat contaminated with bovine spongiform encephalopathy prions, fewer than 200 people worldwide have contracted variant CJD. The incidence of variant CJD has decreased in recent years as the bovine spongiform encephalopathy outbreak in cattle has been contained and the entry of contaminated meat into the food supply restricted.

Most cases of iatrogenic transmission of CJD have involved contaminated cadaveric dura mater allografts, and these have almost all been from a single product, Lyodura, manufactured before May 1987. The other large group of iatrogenic cases occurred in recipients of growth hormone derived from cadaveric pituitaries, before the availability of recombinant growth hormone. Blood and blood products derived from donors with variant CJD have transmitted the illness, but surprisingly, CJD appears not to be transmissible from the blood of persons with the sporadic form of the disease. Contaminated surgical instruments are persuasively documented to have transmitted CJD on only four occasions.

PATHOBIOLOGY

PrP is a cell surface glycoprotein normally produced in the brain and several other tissues in mammals. Its normal function is unknown, but it may play a role in copper metabolism. In prion diseases, an abnormal misfolded and aggregated isoform of PrP, termed PrP^{Sc}, accumulates. Remarkably, PrP^{Sc} is able to recruit the normal form of PrP into the pathologic aggregate. The precise structure of PrP^{Sc} aggregates and the mechanism of prion propagation are incompletely understood, but a basic conceptual model proposes that the normally α-helical regions of PrP directly interact with the β-sheets of PrP^{Sc}, lose their normal structure, and then join the aggregate. At some point, the growing aggregate fractures, thereby creating additional aggregate particles. In this way, aggregates of PrP^{Sc} can propagate as infectious agents.

What precisely initiates sporadic or genetic prion diseases is not known. In infectious forms of prion disease that are transmitted by the alimentary route, prions first replicate in the enteric lymphatic system, including Peyer's patches. From the lymphatic system, prions spread to the CNS via sympathetic nerves in lymphatic tissue. Once in the CNS, prions appear to spread trans-synaptically. As with other neurodegenerative diseases associated with accumulations of aggregated proteins (e.g., β-amyloid in Alzheimer's disease), the mechanism by which the formation PrP^{Sc} causes neuronal dysfunction and death is unknown.

Pathology

Traditionally, prion diseases are recognized by a combination of vacuolization or "spongiosus" of the gray matter, astrocytic gliosis, and loss of neurons. In modern practice, the presence of PrP^{Sc}, demonstrated by immunohistochemical or biochemical techniques, is the pathologic hallmark of these conditions. In some forms of prion disease, PrP^{Sc} will form amyloid plaques, which are dense aggregates of protein linked by intermolecular β-sheets that bind Congo red. However, most commonly the PrP^{Sc} aggregates are smaller and more diffuse.

Genetics

All inherited forms of prion disease are caused by mutations in the PrP coding sequence of the gene *PRNP*. Mutations associated with familial forms of prion disease include more than 20 missense mutations, 2 premature stop mutations, and a series of insertions that code for an additional series of eight amino acids in a region where five of these octapeptide repeats normally occur. Genetic forms of prion disease are transmitted in an autosomal dominant pattern, usually with high but incomplete penetrance. Certain genotypes affect susceptibility to prion disease. Codon 129 of *PRNP* is polymorphic in most populations, with alleles coding for either valine or methionine. Persons who are homozygous (129VV or 129MM) at this allele are overrepresented among victims of sporadic CJD, and all victims of variant CJD (see later) carry 129M on both *PRNP* alleles.

Three distinctive forms of prion disease are associated with certain *PRNP* mutations: Gerstmann-Straüssler-Scheinker syndrome, fatal familial insomnia, and slowly progressive forms of CJD. Gerstmann-Straüssler-Scheinker syndrome is caused by any of several mutations in *PRNP*, the most common of which codes for a substitution of leucine for proline at codon 102 (P102L). Pathologically, there are accumulations of plaques of PrP amyloid in the brain, especially in the cerebellum.

Fatal familial insomnia is caused by a D178N mutation on the same allele as a methionine at the polymorphic codon 129 of *PRNP*. Pathologically, there is neuronal loss and accumulation of PrP^{Sc} in the thalamus. In contrast, the D178N mutation on an allele with valine at codon 129 causes a disease that is indistinguishable from sporadic CJD.

Some *PRNP* mutations cause a slowly progressive dementia. The most common of these mutations are large expansions of the octapeptide repeat region.

CLINICAL MANIFESTATIONS

Sporadic

The most common form of human prion disease is sporadic CJD. Onset is typically in later midlife at an average of about 60 years of age, although onset as young as 17 years and as old as 80 years has been reported. In about 25% of cases, patients or their families report a prodrome of a psychiatric disturbance, such as anxiety, depression, or altered sleep. Cognitive dysfunction is usually the most prominent neurologic sign. Unlike Alzheimer's disease, however, prion disease typically involves other brain systems and causes motor signs (such as ataxia, bradykinesia, or spasticity), vague somatic sensory disturbances, or alterations in visual perception. Myoclonus is a characteristic but not pathognomonic sign. Perhaps the most distinctive feature of prion disease is the pace of its progression. Typically, clear decrements in neurologic function can be observed over a period of weeks.

Genetic

Most genetic forms of prion disease are accompanied by symptoms indistinguishable from the those of the common sporadic syndrome just described. However, the mean age at onset may be somewhat younger.

In Gerstmann-Straüssler-Scheinker syndrome, the clinical signs are prominent ataxia, a slower rate of progression than occurs with sporadic CJD (typically 5 to 6 years from onset to death), and late dementia. Fatal familial insomnia begins with anxiety, depression, and sleep disturbance. Ataxia or other motor signs may also develop early in the disease course. Dementia occurs relatively late in the condition. Very rarely, a sporadic form of CJD will be manifested as a clinical syndrome of sporadic fatal insomnia that is indistinguishable from fatal familial insomnia.

Slowly progressive CJD may have clinical manifestations similar to those of familial Alzheimer's disease (Chapter 409) or resemble Huntington's disease (Chapter 417).

Infectiously Acquired

The extremely rare infectiously acquired forms of prion disease have features that are different from the common sporadic manifestation. The three infectiously transmitted forms of prion disease are variant CJD, kuru, and iatrogenic CJD.

Variant CJD is distinguished clinically from sporadic CJD by a much younger mean age at onset (mean, 26 years; range, 12 to 74 years), the prominence of psychiatric and sensory signs early in the disease, and the later emergence of dementia and motor signs, typically more than 6 months after the first symptoms. Iatrogenic CJD usually resembles sporadic CJD, but a subset of patients may have an ataxic form that clinically and pathologically shares some features with Gerstmann-Straüssler-Scheinker syndrome.

Kuru begins with limb pain followed by cerebellar ataxia and tremor ("kuru" means "shiver" in the Fore language). Overt dementia occurs late in the disease course.

DIAGNOSIS

The diagnosis of prion disease should be considered in patients with relatively rapidly progressive dementia, especially when structural, inflammatory, and more common metabolic, endocrine, and deficiency diseases have been excluded (Table 424-1). If the initial evaluation fails to yield an alternative diagnosis, a number of available tests further support the diagnosis of prion disease. However, prion diseases are rare, and ancillary tests have less than perfect specificity and sensitivity; if they are applied indiscriminately, these

TABLE 424-1 EVALUATION OF RAPIDLY PROGRESSIVE DEMENTIA

Initial screening	**Serum tests:** glucose, sodium, calcium, blood urea nitrogen, creatinine, hepatic aminotransferases, albumin, prothrombin time, TSH, antinuclear antigen, vitamin B_{12}, HIV and syphilis serology **Imaging:** brain MRI **CSF:** glucose, protein, cell counts, VDRL
Test findings supporting a diagnosis of prion disease	**MRI:** T2 hyperintensity in the basal ganglia, sometimes in the cortex **CSF 14-3-3 protein:** elevated levels fairly specific for CJD **EEG:** Periodic sharp wave complexes

CJD = Creutzfeldt-Jakob disease; CSF = cerebrospinal fluid ; EEG = electroencephalography; HIV = human immunodeficiency virus; MRI = magnetic resonance imaging; TSH = thyroid-stimulating hormone; VDRL = Venereal Disease Research Laboratory test.

TABLE 424-2 DIFFERENTIAL DIAGNOSIS OF RAPIDLY PROGRESSIVE DEMENTIA

Neurodegenerative diseases that may mimic CJD	Alzheimer's disease, diffuse Lewy body disease, frontotemporal dementia, corticobasal ganglion degeneration, progressive supranuclear palsy
Some less common treatable diseases that mimic CJD	**Autoimmune:** central nervous system vasculitis, limbic encephalitis, Hashimoto's encephalopathy, anti–voltage-gated potassium channel encephalopathy **Infections:** viral encephalitis, chronic meningitis **Toxicities:** lithium, bismuth, methotrexate **Neoplasms:** primary central nervous system lymphoma, intravascular lymphoma **Structural:** Normal-pressure hydrocephalus

CJD = Creutzfeldt-Jakob disease.

tests will frequently yield false-positive results. The presence of elevated cerebrospinal fluid levels of a protein called 14-3-3 is relatively specific for CJD if inflammatory and ischemic causes of dementia are excluded. An unusual hyperintensity of the deep gray matter (basal ganglia and thalamus) and sometimes the cortical gray matter on certain magnetic resonance imaging sequences (T2-weighted, fluid-attenuated inversion recovery, and diffusion-weighted weighting) occurs in about two thirds of CJD cases. The electroencephalogram in patients with CJD may show a pattern of periodic large-amplitude triphasic complexes.

Most diseases that cause rapidly progressive dementia are, like prion disease, untreatable and relentlessly progressive, for example, atypical Alzheimer's disease and diffuse Lewy body dementia (Table 424-2). However, it is important to exclude rare and at least partially treatable entities that can mimic prion disease, including autoimmune, infectious, toxic, malignant, and structural causes.

Certain diagnosis of prion disease can be made by brain biopsy. Tissue is examined immunohistochemically for the presence of abnormal aggregates of PrP. National or regional specialized prion disease centers, such as the National Prion Disorders Pathology Service Center (available at *http://www.cjdsurveillance.com*) in the United States, can assist pathologists in tissue analysis. In patients with a family history of neurodegenerative disease consistent with prion disease, determining the sequence of the protein-coding region of the prion protein gene can be diagnostic if a mutation is found.

TREATMENT AND PROGNOSIS

Rx

Prion diseases are incurable, and no treatment significantly improves the course of disease. Most patients with sporadic CJD die within a year of the onset of symptoms. Patients with Gerstmann-Straüssler-Scheinker syndrome and certain other genetic or variant forms of prion disease may live longer. Excellent animal models of prion disease exist, and a number of novel therapeutic approaches are under active investigation. It is worthwhile to consider enrollment in experimental clinical trials if they are available (*http://clinicaltrials.gov*).

PREVENTION

Most cases of prion disease occur sporadically and cannot be prevented. Genetic cases can potentially be prevented through genetic counseling and prenatal testing, although whether such measures are warranted to prevent a disease that may not be manifested until midlife or later is an ethically complex question. Infectiously transmitted cases are currently amenable to preventive measures, including avoidance of surgical transmission as a result of contaminated instruments or tissue grafts and protection of the human food supply from meat products contaminated with bovine spongiform encephalopathy or other ruminant prions. Chronic wasting disease is epidemic among deer and elk in certain regions of the United States, and scrapie, which affects sheep and goats, is endemic at low levels in the United States and many other countries. Neither of these prion diseases has been convincingly linked to human illness, but prudence dictates that humans should avoid eating any prion-infected animal.

NUTRITIONAL AND ALCOHOL-RELATED NEUROLOGIC DISORDERS

BARBARA S. KOPPEL

An adequate supply of vitamins and minerals is necessary for development and metabolic function of both the central and peripheral nervous systems. Deficiencies of vitamins and minerals can cause a variety of neurologic syndromes (Table 425-1).

Vitamin deficiency (Chapter 225) can be caused by either malnutrition (Chapter 222) or malabsorption (Chapter 142). In malnutrition, it may be difficult to determine the specific vitamin responsible for particular neurologic symptoms and signs because multiple deficiencies are likely to coexist. Malnutrition is the most common cause of vitamin deficiency in economically disadvantaged countries. When adequate food supplies are readily available, malnutrition may be caused by surgery for obesity, unbalanced ("fad") diets, prolonged vomiting or anorexia, excess alcohol consumption, incomplete parenteral nutrition, or a genetic predisposition to malabsorption or dysfunction of transport proteins.

DEFICIENCY OF WATER-SOLUBLE VITAMINS

Thiamine (Vitamin B_1) Deficiency

Thiamine is converted to thiamine pyrophosphate, which serves as a coenzyme in glucose and lipid metabolism and in the synthesis of neurotransmitters from branched-chain amino acids. To avoid deficiency, thiamine must be consumed regularly in adequate amounts.

BERIBERI

In developing countries, the most common manifestation of thiamine deficiency is beriberi, which results in a painful sensorimotor peripheral neuropathy and heart failure ("wet beriberi"). Other causes of thiamine deficiency include consumption of foods in which the vitamin has been inactivated by processing or overcooking or foods that contain thiaminase-producing bacteria (e.g., raw fish). Headache, vomiting, seizures, and cranial nerve dysfunction can develop in babies born to malnourished mothers or fed thiamine-deficient formula.

TABLE 425-1 SUMMARY OF VITAMIN AND MINERAL DEFICIENCIES

VITAMIN AND MINERAL DEFICIENCIES	NEUROLOGIC SYNDROME OR SYNDROMES	SUPPORTING TESTS	TREATMENT	CAUSES (OTHER THAN MALNUTRITION)
A (Retinol)	Blindness from retinal or corneal damage	Visual fields, visual acuity Serum level <30-65 µg/dL	30,000 IU vitamin A daily × 1 wk	Hypothyroidism, diabetes, renal or liver failure
B_1 (thiamine)	Wernicke's encephalopathy: ataxia, nystagmus, ophthalmoparesis, confusion, delirium Korsakoff's syndrome: amnesia, confabulation Beriberi: axonal neuropathy	MRI: symmetrical lesions of midbrain (periaqueductal area), pons, hypothalamus, thalamus, cerebellum MRI: necrosis of mamillary bodies, dorsomedial and anterior thalamus Nerve conduction tests: decreased amplitude Serum thiamine level <20 ng/dL Erythrocyte transketolase	Prevent by 100 mg PO daily before and 1 year after bariatric surgery, 100 mg IV before glucose administration or refeeding Treat Wernicke's encephalopathy with 5 days of thiamine, 100-500 mg IV or IM daily, then PO 100 mg daily Antioxidants (*N*-acetylcysteine)	Alcoholism, bariatric or other major GI surgery, prolonged vomiting, hemodialysis, diuretic treatment of heart failure, cachexia, 5-fluorouracil, other blockers of thiamine phosphate production
B_3 (niacin)	Pellagra: confusion, dementia, weakness, ataxia, spasticity, myoclonus, glossitis, dermatitis, photosensitivity	Erythrocyte NAD, plasma niacin, urinary N1-methylnicotinamide	Nicotinic acid, 50 mg PO tid or 25 mg IV tid; nicotinamide, 50-100 mg IM or PO tid	Alcoholism, corn- or cereal-based diet, Hartnup's syndrome, carcinoid syndrome
B_5 (pantothenic acid)	Dysesthesias, foot paresthesias	Deficient coenzyme A	5 mg PO daily	Severe malnutrition
B_6 (pyridoxine)	Neuropathy, sensory ataxia, depression Infantile pyridoxine-deficient epilepsy	Plasma PLP <27 nmol/L; urinary 4-pyridoxic acid, <3 nmol ↑ Homocysteine after methionine loading challenge ↑ α-AASA in urine, plasma, CSF	50-100 mg PO daily for neuropathy (preventive use if taking B_6 antagonist) 100-200 mg daily for adult epilepsy	Diverticulosis, isoniazid, cycloserine, other antagonists Genetic defects in antiquitin (aldehyde dehydrogenase), pyridoxal synthesis
B_{12} (cobalamin)	Myelopathy with spastic paraparesis and sensory ataxia, peripheral neuropathy, optic neuropathy, memory loss, dementia; indirect contributor to stroke	Blood level <200 pg/mL ↑ Methylmalonic acid >145 nmol/L Intrinsic factor antibodies Schilling test, megaloblastic anemia Delayed somatosensory evoked potentials ↑ Homocysteine, total >12.5 µmol/L	IM B_{12}, 1000 µg daily for 1 week, then weekly for 1 month, then monthly or oral B_{12}, 1000 µg daily, or nasal B_{12}, 500 µg weekly for lifetime if abnormal absorption, 50-100 µg daily if normal absorption	Achlorhydria, gastric or ileal resection, blind loop syndrome, sprue, HIV infection, nitrous oxide anesthesia (especially abuse), fish tapeworm, vegan diet
D (calciferol)	Proximal myopathy, often painful; cognitive impairment Secondary compression of spinal cord, plexus, or peripheral nerves from rickets or osteomalacia	25-(OH) vitamin D_3 level <10 ng/mL in urine Serum calcium ↑ PTH >54 pg/mL Osteopenia/porosis on bone densitometry	Daily supplementation with 400 IU, >50,000 IU 3 times per wk if malabsorption; use blood level or urine calcium excretion to guide (should be >100 mg/day)	Lack of exposure to sunlight, including sunblock protection; chronic antiepileptic drug use
E (tocopherol)	Spinal and cerebellar ataxia, Babinski's sign, ophthalmoplegia, peripheral neuropathy, retinitis pigmentosa	Vitamin E level <2.5 mg/L (normal, 6-15 with normal lipid level) ↑ A-β-lipoprotein levels, antigliadin antibodies Genetic analysis to rule out other spinocerebellar ataxias such as Friedreich's ataxia	Supplement with 6-800 IU, 5-10 mg/kg twice daily, for ataxia of genetic causes, water-soluble 200 mg/kg/day or IM α-tocopherol for malabsorption	Biliary atresia, celiac sprue, Genetic: ↓ α-tocopherol transport protein (8q13), microsomal triglyceride transfer protein
Folate	Dementia, B_{12} deficiency, stroke	↑ Homocysteine, plasma level <2.5 µg/L	1 mg 3 times per day until normal level, then maintenance of 1 mg/day Pregnancy: additional 0.4 mg/day if taking a folate antagonist	Malabsorption or use of antagonist (methotrexate) or antiepileptic medication
K (phytonadione)	Intracranial hemorrhage	INR or PT elevation	IM phytonadione at birth, maternal vitamin K for last month of pregnancy	Medication use that increases metabolism, such as phenytoin
Copper	Myelopathy, neuropathy	Serum Cu <75 µg/dL, ↓ urinary Cu, ceruloplasmin <23 mg/dL MRI: ↑ T2 signal in cervical cord, dorsal column Mutation in *ATP7A* gene (Menkes' disease)	Elemental Cu, 8 mg/day PO week 1, 6 mg/day week 2, 4 mg/day week 3, 2 mg/day ongoing malabsorption Menkes' disease: 250 mg SC bid	Wilson's disease, Menkes' disease, alcoholism, malabsorption, gastric bypass, zinc toxicity
Magnesium	Seizures, encephalopathy	Serum magnesium <1.5 mg/dL, correct for low albumin	Magnesium sulfate IV or PO Avoid magnesium-wasting drugs	Alcoholism, especially beer
Potassium	Muscle weakness, chronic, acute	Serum potassium <3.5 mEq/L, ECG	IV or PO KCl until normalized	Diuretic use, bulimia

AASA = aminoadipic semialdehyde; CSF = cerebrospinal fluid; ECG, electrocardiography; GI = gastrointestinal; INR = international normalized ratio; MRI = magnetic resonance imaging; NAD = nicotinamide adenine dinucleotide; PLP = pyridoxal-5-phosphate (active coenzyme of pyridoxine); PT = prothrombin time; PTH = parathyroid hormone.

WERNICKE'S ENCEPHALOPATHY

Severe short-term thiamine deficiency results in Wernicke's encephalopathy, a syndrome characterized by confusion and other changes in mental status, abnormal eye movements, and ataxia. Wernicke's encephalopathy occurs most commonly in the setting of chronic alcohol abuse, but it can also be seen following bariatric surgery, refeeding after a period of starvation, or after the intravenous administration of glucose without thiamine. The symptoms and signs of Wernicke's encephalopathy reflect dysfunction of brain regions that are dependent on thiamine or have high rates of energy metabolism, where lactate production from anaerobic metabolism causes damage to astrocytes or the blood-brain barrier. These regions include the periaqueductal gray matter of the midbrain, pons, and medulla, as well as the cerebellum,

anterior thalamus, mamillary bodies, and rarely, the cerebral cortex and hypothalamus.

The classic triad of mental status changes, ocular abnormalities, and ataxia is present in less than 50% of patients. Changes in mental status range from mild memory impairment or inattention to delirium. Eye movement abnormalities include nystagmus, dysconjugate gaze, and gaze palsies. Ataxia can affect the limbs, trunk, and gait. Patients with Wernicke's encephalopathy can also have autonomic and hypothalamic dysfunction, such as bradycardia and hypothermia, as well as papilledema, optic neuropathy, seizures, and myoclonus. In symptomatic patients, T2-weighted magnetic resonance imaging (MRI) demonstrates increased signal from edema or hemorrhage in affected areas, most often the thalamus.

KORSAKOFF'S SYNDROME

Korsakoff's syndrome becomes apparent in 80% of patients with Wernicke's encephalopathy as the ataxia and eye movement abnormalities improve. Korsakoff's syndrome is characterized by disproportionate retrograde and anterograde episodic amnesia, confabulation or hallucinations, and sometimes apathy. The primary pathologic findings occur in the limbic system, especially the mamillary bodies, amygdala, and anterior thalamus.

The memory deficit, which prevents the learning of new information or the acquisition of new memories, is disproportionately severe in relation to other aspects of the cognitive function. For example, alertness, attention, social interactions, and motor learning are generally well preserved. There may be mild disorientation with respect to time and place, and sometimes apathy and other emotional changes are present. Confabulation, in which the intrusion of errors in response to questions leads to fabrication without the intention of deceiving, is often present spontaneously in the first weeks. Confabulation may be a compensatory mechanism, and it usually lessens over time. Neuropsychological testing often demonstrates emotional changes and mild problems in executive function, which are suggestive of frontal lobe involvement.

TREATMENT Rx

Treatment with thiamine (see Table 425-1) can prevent or treat beriberi and Wernicke's encephalopathy. Korsakoff's syndrome, however, does not respond to replacement of thiamine and must be prevented by timely recognition and treatment of Wernicke's encephalopathy.

Cobalamin (Vitamin B_{12}) Deficiency

Cobalamin deficiency results in combined system disease or subacute combined degeneration, which is a spinal cord syndrome (myelopathy) in which damage to the dorsal (sensory) and lateral (motor) tracts results in impaired position and vibratory sensation and spastic paraparesis.

EPIDEMIOLOGY AND PATHOBIOLOGY

Cobalamin deficiency (Chapters 167 and 225) is most common in individuals older than 60 years because the incidence of atrophic gastritis (Chapter 141) and achlorhydria rises in older individuals who lack the gastric intrinsic factor needed for absorption of vitamin B_{12}. Cobalamin deficiency is rarely due to inadequate dietary intake (e.g., a vegan diet for several years). Nitrous oxide toxicity, from illicit use but not from administration for anesthesia, can cause cobalamin deficiency by inactivating the cobalamin-dependent enzyme methionine synthase, so this anesthetic should be avoided in people with known or suspected cobalamin deficiency. Low vitamin B_{12} levels have been associated with increased homocysteine levels, but a relationship to vascular disease or vascular-related dementia has not been established.

CLINICAL MANIFESTATIONS

The proprioceptive loss results in sensory ataxia with Romberg's sign (failure to maintain balance with the eyes closed). A peripheral neuropathy with numbness and tingling in the hands and feet is almost always present. Cerebral involvement includes memory loss, changes in personality, and occasional psychosis. Symptoms generally progress slowly, but they may appear especially rapidly after exposure to nitrous oxide anesthesia by individuals with preexisting subclinical cobalamin deficiency.

DIAGNOSIS

Serum vitamin B_{12} levels are almost always low but can rarely be normal in symptomatic patients. In such cases, serum levels of methylmalonic acid and homocysteine are useful ancillary tests because these levels are increased in persons with vitamin B_{12} deficiency as a result of impaired cobalamin-dependent reactions (Chapter 167). Pernicious anemia (Chapter 167) is severe in about 20% of patients. However, both the hematocrit and mean corpuscular volume can be normal because the hematologic effects of cobalamin deficiency can be partially masked by folate supplementation.

Low levels of cobalamin can also be present in many normal people, especially the elderly. Because of the increasing frequency of dementia, peripheral polyneuropathy, and myelopathy with age, a low cobalamin level does not necessarily imply cause and effect. Nonetheless, the triad of dementia, polyneuropathy, and myelopathy is rare. The definitive definition of causality is clinical improvement after cobalamin replacement.

TREATMENT Rx

Treatment usually begins with a subcutaneous or intramuscular injection of 500 to 1000 µg of cobalamin daily for 1 week and then weekly for 1 month. After that time, oral supplementation with 50 to 100 µg daily of cyanocobalamin usually suffices in patients with achlorhydria or other causes of malabsorption; 1000 µg daily should be used in patients with intrinsic factor antibodies. A nasal gel form (500 µg weekly) may also be effective.

PROGNOSIS

Neurologic symptoms, especially paresthesias, typically improve to some extent within 3 months of achieving adequate serum levels. Numbness and areflexia often persist, especially if treatment is delayed. If there is no improvement whatsoever, vitamin B_{12} deficiency is most likely not responsible for the condition. For example, human immunodeficiency virus–associated myelopathy, which can have a similar clinical manifestation, does not reverse with supplemental vitamin B_{12} because it is caused by disruption of transmethylation pathways, not low cobalamin levels (see Table 425-1).

Folate Deficiency

Folate is an important coenzyme in the metabolism of nucleic and amino acids. Inborn errors of folate metabolism cause mental retardation and seizures. Although folate deficiency is more likely to produce hematologic abnormalities than neurologic deficits, it is an important risk factor for neural tube defects in babies born to mothers who have insufficient folate intake or use anticonvulsant drugs such as valproate, antituberculosis medications, or folate antagonists such as methotrexate. Women of childbearing age who are taking these medications are now routinely given 0.4 mg of folate daily in addition to the 1 mg contained in prenatal vitamins. Vitamin B_{12} levels should be checked to avoid ongoing neurologic damage as a result of unrecognized cobalamin deficiency when anemia is treated with folate alone. Folate deficiency is treated with 1 mg three times daily for 1 month followed by 1 mg each day.

Folate deficiency results in increased levels of homocysteine, which is associated with an increased risk for ischemic heart disease and stroke. However, multiple trials of supplementation of folate and B vitamins in patients with elevated homocysteine levels but not with classic homocysteinemia have been uniformly unsuccessful in reducing adverse clinical events.

Pyridoxine (Vitamin B_6) Deficiency

Pyridoxine is a coenzyme in multiple reactions that involve gluconeogenesis, biosynthesis of neurotransmitters, and the metabolism of amino acids, nucleic acids, and lipids. Pyridoxine deficiency can be caused by genetic defects, such as defective antiquitin, that lead to increased utilization of pyridoxine. In adults, low levels of pyridoxine are well tolerated, so symptomatic deficiency is rare. However, symptomatic deficiency can occur in the setting of renal failure or dialysis; cirrhosis; the use of medications such as isoniazid for antitubercular therapy or hydralazine for hypertension without concurrent supplementation; or extreme malnutrition, especially diets consisting predominantly of white rice.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Prolonged pyridoxine deficiency causes a painful axonal peripheral neuropathy that leads to weakness and sensory ataxia. Some patients may have skin thickening, seborrheic dermatitis, or glossitis, which suggest pellagra. Serum levels of the active form of pyridoxine, pyridoxal 5′-phosphate, and urine levels of the metabolite 4-pyridoxic acid are low. Ancillary tests include nerve

conduction studies, which show decreased amplitude, typical of axonal neuropathy. In inherited forms of pyridoxine deficiency, electroencephalography shows generalized 1- to 4-Hz spiked wave discharges and slowing.

Toxicity from excess intake of pyridoxine (>100 mg daily), usually from vitamin supplements, causes a ganglionopathy that is characterized by impaired sensation, sensory ataxia with Romberg's sign, and areflexia.

TREATMENT Rx

Patients in whom symptoms of pyridoxine deficiency develop or who take pyridoxine antagonists should receive supplemental pyridoxine (50 to 100 mg daily). Children with pyridoxine-dependent epilepsy require lifelong supplementation with 100 mg of pyridoxine daily. For pyridoxine toxicity, simply stopping vitamin intake will usually reverse the damage.

DEFICIENCY OF FAT-SOLUBLE VITAMINS

Vitamin E (Tocopherol) Deficiency

Although vitamin E is composed of several tocopherols, it is the α form that is biologically active in humans and contained in most foods. Because it is so widely available, deficiency is almost never due to inadequate dietary consumption. Rather, vitamin E deficiency is almost always the result of malabsorption because of such conditions as biliary and pancreatic disease (Chapters 158 and 146), cystic fibrosis (Chapter 89), celiac disease (Chapter 142), Crohn's disease (Chapter 143), extensive small bowel resection, and blind loop syndrome (Chapter 142). In addition, vitamin E deficiency is associated with genetic defects such as those causing hypolipoproteinemia and abetalipoproteinemia, chylomicron retention disease, and ataxia with vitamin E deficiency.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Neurologic manifestations of vitamin E deficiency include a spinocerebellar syndrome with ataxia, loss of vibration and position senses, hyporeflexia, and extensor plantar responses. Other findings can include ophthalmoplegia, retinopathy, ptosis, and rarely, myopathy.

Serum levels of vitamin E can vary with the serum lipid levels. In extreme hyperlipidemia, such as cholestasis, the ratio of vitamin E to cholesterol will be more reliable than the absolute vitamin E level, which can be normal despite a low ratio.

TREATMENT Rx

The amount of vitamin E replacement depends on the cause. Malabsorption syndromes require 1000 to 2000 mg daily for infants and 10 to 20 g for adults. Genetic causes can be treated with 5 to 10 g/day. After bariatric surgery, 300 mg daily is recommended. For vitamin E, 1 mg is equivalent to 1.49 IU. Although vitamin E has been advocated to forestall neurodegenerative diseases such as Alzheimer's disease, this role has not been established.■

Vitamin D (Calciferol) Deficiency

Vitamin D deficiency results from inadequate exposure to sunlight, dietary insufficiency, or malabsorption because of celiac disease, inflammatory bowel disease, or extensive small bowel resection. The most important consequences of vitamin D deficiency are rickets in children, osteomalacia in adults, and hypocalcemia with secondary hyperparathyroidism. Hypocalcemia, in turn, can cause tetany, encephalopathy, and seizures. A proximal myopathy, worse in the legs than the arms, and cutaneous hyperalgesia have been reported. Inadequate vitamin D levels, present in 44% of Americans older than 65 years, are associated with cognitive dysfunction or dementia. Lower levels of vitamin D are also correlated with the risk for multiple sclerosis (Chapter 419). Individuals who can absorb vitamin D normally require 400 to 600 IU of vitamin D_3 (cholecalciferol) (10 to 15 μg), but persons with malabsorption may need more than twice that amount. The eventual dose should be titrated to produce a serum 25-hydroxyvitamin D level of at least 30 ng/mL.

Vitamin A Deficiency

Vitamin A deficiency, which is most often associated with night blindness, can also impair taste and has rarely been associated with raised intracranial pressure in children. Malabsorption rarely leads to vitamin A deficiency. Vitamin A toxicity, which is occasionally a complication of the use of isotretinoin for acne or excessive consumption of liver in the diet, can cause pseudotumor cerebri with headache and papilledema.

Vitamin K Deficiency

Vitamin K deficiency, which is a rare consequence of malabsorption, is seen more commonly in patients who have compromised liver synthesis or who are receiving warfarin therapy. Vitamin K deficiency causes excessive bleeding and increases the risk for intracerebral hemorrhage (Chapter 415), especially in newborns whose mothers are taking antagonists such as phenytoin. Five milligrams daily is usually adequate supplementation, but the dose may need to be adjusted based on the prothrombin time.

DEFICIENCY OF MISCELLANEOUS ELEMENTS AND NUTRIENTS

Copper Deficiency

Acquired copper deficiency is rare but may occur in premature or malnourished infants and in patients with malabsorption from celiac disease, cystic fibrosis, or Crohn's disease. It can also occur in patients with nephrotic syndrome and following gastric surgery, especially bariatric surgery. Copper deficiency is also a well-recognized consequence of excessive intake of zinc, usually as a result of the overuse of zinc-containing products, such as denture cream or herbal preparations to treat rhinitis and sinusitis, or because of parenteral overload during hemodialysis.

The most common neurologic complication in persons with copper deficiency is a myelopathy that is clinically very similar to that seen with cobalamin deficiency. The most prominent features are spastic paraparesis and sensory ataxia. A peripheral polyneuropathy of the axonal type is usually present as well. Copper levels, including excreted urinary copper, should be measured in patients who are suspected of having vitamin B_{12} deficiency but fail to respond to treatment with cyanocobalamin. Optic neuropathy, wristdrop, and footdrop have also been reported. Menkes' disease, an X-linked recessive copper deficiency caused by mutations in the *ATP7A* gene needed for absorption, is characterized by severe mental retardation and kinky hair. The diagnosis is made by finding low serum copper levels or changes in the ratio of dopamine to norepinephrine. Large doses of copper histidine (250 mg twice daily until age 1, then daily until age 3) must be delivered subcutaneously, but improvement is variable. Patients survive to adulthood only if copper injections start neonatally.

Wilson's disease (Chapter 218) is an autosomal recessive disorder that results from excessive copper accumulation, primarily in the liver and brain, as a result of failed transport and impaired copper excretion. Ceruloplasmin, the transport protein for copper, is deficient. Neurologic manifestations can include depression, psychosis, dementia, dysarthria, tremor, chorea, and other movement disorders. Accumulation of copper in the liver leads to chronic liver failure. Wilson's disease is treated by copper chelation (Chapter 218) and by minimizing dietary intake.

Other Nutritional Disorders

Biotin deficiency is caused by an autosomal recessive disorder affecting biotinidase. It results in developmental delay, seizures, ataxia, and deafness.

Some epidemics that are manifested as peripheral neuropathy or optic neuropathy, such as Strachan's Jamaican neuropathy and Cuban tobacco-alcohol amblyopia, occur in the setting of malnutrition and respond to replacement of B vitamins or folate. Toxicity from foods should always be suspected in populations that are reliant on a single main source of nutrition, even when the exact cause is not known. Examples include spastic paraparesis or muscle atrophy from overconsumption of legumes in the *Lathyrus* genus, such as chick peas, which contain the neurotoxic glutamate agonist oxalyldiaminoproprionic acid; konzo, probably from cyanide poisoning (Chapter 110), which is related to improperly prepared cassava in Africa; and amyotrophic lateral sclerosis and Parkinson-dementia complex in Guam, probably caused by cycad toxins in flour.

ALCOHOL-RELATED DISORDERS

Alcohol (Chapter 32) is responsible for a wide spectrum of neurologic disorders. At one extreme, it can cause irreversible dementia, cerebellar degeneration, optic neuropathy, and peripheral polyneuropathy. Alcohol also causes transient neurologic syndromes such as seizures, tremors, hallucinosis, and delirium tremens. Acute intoxication can range from mild euphoria,

to vestibular and cerebellar dysfunction, to coma and death. When alcohol is the main source of calories, it contributes to nutritional deficiency syndromes such as Wernicke-Korsakoff syndrome, beriberi, and pellagra. Alcohol-induced liver toxicity results in hepatic encephalopathy and non-wilsonian hepatolenticular degeneration. Coagulopathy caused by liver disease or suppressed platelet production raises the risk for subdural or intracranial hematoma. Fetal alcohol syndrome reflects the vulnerability of the developing nervous system to the toxic effects of alcohol.

Signs of intoxication correlate with blood alcohol levels: from 50 mg/dL for personality changes; 150 mg/dL for ataxia, vestibular dysfunction, and nystagmus; 300 mg/dL for stupor; 400 mg/dL for coma; and up to 500 mg/dL for respiratory depression or apnea. However, the effects vary greatly, depending on the chronicity of intake and the rate at which high levels develop. Intoxication alone should never be assumed to be the sole cause of a depressed mental state because alcoholics are at increased risk for other causes of coma (Chapter 411).

Specific Clinical Syndromes

Seizures and status epilepticus (Chapter 410) can be a direct consequence of intoxication, withdrawal, hyponatremia (Chapter 118), and hypomagnesemia (Chapter 121) or result from epileptogenic foci from previous head trauma or stroke.

Hepatic encephalopathy can be the result of alcoholic cirrhosis (Chapter 156), especially in patients who have bleeding esophageal varices, and is characterized by irritability alternating with depressed mental status, seizures, tremor, and asterixis.

Dementia develops even when nutrition is well maintained because of alcohol's direct neurotoxic effects. Contributing factors include head injury, status epilepticus, and cerebrovascular disease. Further evidence of alcohol's deleterious effect is cerebral atrophy involving both gray and white matter. The dementia is probably not reversible.

Wernicke's encephalopathy and *Korsakoff syndrome* are described in the section on thiamine.

Marchiafava-Bignami syndrome was first described in postmortem studies of Italian chianti drinkers but can occur in persons who consume any type of alcohol. Acute signs include coma, seizures, hemiparesis, rigidity, and sometimes death. The most severe pathology involves demyelination and necrosis of the corpus callosum. Findings on MRI include increased T2- and diffusion-weighted signals in the corpus callosum, especially the splenium.

Cerebellar degeneration and ataxia result from the alcohol-induced loss of Purkinje cells, mainly in the anterior superior parts of the cerebellar vermis; the cerebellar hemispheres are less affected. As a result, the clinical picture is mainly truncal and gait ataxia, with a wide-based unsteady gait and inability to walk tandem. The arms are much less involved, if affected at all. Intention tremor, nystagmus, and dysarthria are rare. Findings are exacerbated by concurrent thiamine deficiency and Wernicke's encephalopathy.

Optic neuropathy, which occurs with severe chronic alcohol abuse, is manifested as progressive, painless visual loss as a result of damage to the optic nerve fibers. The macular region is most affected. Similar findings, first described in Cuban men who were heavy cigar smokers, have also been attributed to tobacco. However, neither alcohol nor tobacco is apparently directly responsible for the optic nerve damage, so it is more likely that the syndrome results from malnutrition and deficiencies of multiple vitamins, including vitamins A and B.

Peripheral neuropathy (Chapter 428) ("alcoholic neuropathy") is the most common neurologic complication of chronic alcoholism. It is an axonal sensorimotor neuropathy that causes dysfunction of small nerve fibers, thereby leading to distal sensory symptoms such as burning dysesthesias and paresthesias of the soles of the feet. The typical numbness develops in a stocking-glove distribution, with loss of ankle reflexes. Mild distal weakness eventually occurs in some patients. Involvement of the autonomic nervous system frequently causes impotence, as well as urinary or bowel complaints. Although vitamin supplements, especially thiamine and pyridoxine, may lead to some improvement, especially in the painful paresthesias, complete resolution is rare. If abstinence from alcohol is not also achieved, the symptoms persist, thereby implying that a direct toxic effect of alcohol is likely.

Compressive neuropathies, especially of the radial nerve ("Saturday night palsy") and peroneal nerve, occur in individuals who injure peripheral nerves during periods of prolonged pressure on a nerve while obtunded from heavy alcohol consumption. Recovery takes several weeks but is generally complete.

Myopathy occurs in binge drinkers, in whom severe muscle injury with rhabdomyolysis (Chapter 115) can develop, especially in the setting of fasting and prolonged absence of movement. Myoglobinuria can result in kidney damage. Heavy alcohol consumption is also associated with cardiomyopathy (Chapter 60), which can lead to arrhythmias even in the absence of hypokalemia. Chronic alcohol abuse causes a symmetrical proximal weakness (Chapter 429), but it is rarely the only neurologic finding; although weakness can be demonstrated in up to 50% of chronic alcoholics, it is not usually severe enough to prevent walking or standing.

Fetal alcohol syndrome is recognized at birth in infants whose mothers consumed significant amounts of alcohol, especially in the early stages of pregnancy. The characteristic findings are growth retardation, microcephaly, hypotonia, skeletal and cardiac anomalies, and characteristic facial features (micrognathia, small palpebral fissures). Recently, migration defects have been demonstrated by diffusion-weighted MRI and tractography. Exposure of the developing brain to alcohol can also lead to subtle or severe neurocognitive defects and attention deficit disorder, which may not be detected until later in childhood. The teratogenic effects of alcohol are not prevented by adequate amounts of thiamine, folate, and other vitamins.

CONGENITAL, DEVELOPMENTAL, AND NEUROCUTANEOUS DISORDERS

JONATHAN W. MINK

CONGENITAL DISORDERS

Malformations of Cerebral Cortex

Developmental malformations of the cerebral cortex arise from a wide variety of etiologies, including genetic mutations, intrauterine infections, intrauterine ischemia, and toxic exposures. These malformations are heterogeneous and can result from disrupted neuronal proliferation, migration, or cortical organization. In general, disorders that arise early in development are more severe than those that arise after the basic architecture of the brain has developed. When small areas of the brain are involved, the patient may have minor impairment of neurologic function. When larger areas of the brain are involved, patients often have cognitive deficits and more severe neurologic dysfunction. Epilepsy (Chapter 410), which is the most common manifestation of abnormal cortical development, may occur with or without other neurologic signs or symptoms.

Disorders of Neuronal Proliferation

Neuronal proliferation can be abnormally increased or decreased owing to a variety of mechanisms. These disorders can manifest with megalencephaly or

microcephaly, or head size can be normal. Abnormal proliferation can involve specific cell types, thereby resulting in focal or multifocal areas of dysplasia or in the formation of hamartomas (see Tuberous Sclerosis, later).

FOCAL CORTICAL DYSPLASIA WITH BALLOON CELLS

Focal cortical dysplasia is caused by abnormal proliferation of both neurons and glia. Its neuropathology is characterized by the presence of giant dysmorphic neurons and "balloon cells" associated with altered cortical lamination, but some lesions have abnormal cortical layering with ectopic neurons in white matter. Affected patients typically present with partial seizures that are often intractable to medical therapy. These seizures can begin at any age but most commonly present during childhood or adolescence. The type of seizure depends on the anatomic location of the dysplasia. Other neurologic manifestations, such a sensory, motor, or cognitive impairments, depend on the extent of the dysplasia and whether multiple brain regions are affected. The diagnosis of focal cortical dysplasia is usually made with brain magnetic resonance imaging (MRI), which demonstrates focal thickening of a gyrus or alteration of the gray-white matter junction. Management includes medical treatment of seizures, but surgical resection of the epileptic focus may be required for complete remission (Chapter 410).

Disorders of Neuronal Migration

Disorders of neuronal migration typically result in disruption of the normal laminar organization of the cerebral cortex. Defects include impaired initiation of neuronal migration, impaired orderly migration, and impaired termination of migration. All result in abnormal cortical organization and function.

LISSENCEPHALY AND BAND HETEROTOPIA

The lissencephalies (smooth brain) are a group of disorders that are caused by arrested migration of neurons to the cerebral cortex. Lissencephaly genes include *LIS1* (chromosome 17p13.3) and *DCX* (chromosome Xq22), both of which are thought to be involved in the regulation of microtubule organization and function. Individuals with mutations of *LIS1* typically have severe malformations that are most prominent in the posterior cerebrum. More extensive mutations in the region of *LIS1* result in Miller-Dieker syndrome, a condition characterized by lissencephaly and distinctive facial features that include a prominent forehead, midface hypoplasia, low-set and abnormally shaped ears, and a small jaw. Males with *DCX* mutations typically have a severe lissencephaly that is most prominent in the anterior cerebrum. Lissencephaly is typically diagnosed in infancy or early childhood, usually accompanied by microcephaly, severe global developmental delay, cerebral palsy, and intractable epilepsy. Diagnosis of lissencephaly is made by brain MRI that shows a smooth cortex with minimal sulcation. Genetic testing for *LIS1* and *DCX* is available. Management consists of seizure control, genetic counseling, and supportive care.

Band heterotopia (double cortex) is a less severe form of lissencephaly that is usually seen in women with *DCX* mutation. Clinical manifestations of band heterotopia range from mild to severe and include seizures, intellectual disability, and developmental delay. Women with a *DCX* mutation are at risk of having male children with severe lissencephaly. Brain MRI demonstrates a band of gray matter underlying a nearly normal-appearing cerebral cortex. Management consists of seizure control and genetic counseling.

NODULAR HETEROTOPIA

Nodular heterotopias are characterized by nodular ectopic collections of neurons and glia in the subependyma or in the subcortical white matter. The most important form is subependymal nodular heterotopia, a condition characterized by multiple gray matter nodules in the walls of the lateral ventricles bilaterally. This X-linked condition is due to a mutation in *FLNA* (chromosome Xq28), which codes for filamin A, an actin-cross-linking phosphoprotein that is critical for the initiation of migration. As a result of this mutation, many neurons do not migrate out of the subventricular zone. Most affected individuals are heterozygous females. Males are severely affected and often die in infancy. Most affected females present with seizures during childhood or adolescence. Females may be intellectually normal or have mild disability. Individuals with subependymal nodular heterotopia appear to be at increased risk for aortic or carotid dissection and for cardiac valvular abnormalities.

The diagnosis is based on brain MRI, which shows gray matter nodules along the walls of the lateral ventricles. Genetic testing for FLNA is available. Management consists of seizure control and genetic counseling.

Disorders of Cortical Organization

Disorders of cortical organization include conditions such as polymicrogyria and schizencephaly. These disorders are not due to abnormal numbers of neurons or impaired migration but instead include abnormalities of gyration, sulcation, connectivity, or synaptogenesis. The best understood of these disorders are polymicrogyria and schizencephaly.

POLYMICROGYRIA

Polymicrogyria is characterized by regions of complex cortical convolutions with miniature gyri that are fused and superimposed together. Polymicrogyria is caused by failure of cortical organization as a result of in utero injury or genetic mutation; it has been associated with prenatal infections, such as cytomegalovirus, and possible vascular abnormalities, but often it is idiopathic. A single gene, *GPR56* (chromosome 16q13), has been associated with bilateral frontoparietal polymicrogyria. *GPR56* codes for a G protein–coupled receptor that appears to be important for human cerebral cortical development. Clinical manifestations include epilepsy, developmental delay, cerebral palsy, and intellectual disability, depending on the location and extent of the abnormality. The diagnosis of polymicrogyria is made by brain MRI. Clinical management consists of seizure management and supportive therapies.

SCHIZENCEPHALY

Schizencephaly is characterized by infolding of cortical gray matter along a hemispheric cleft near the primary cerebral fissures. It is thought to represent a more extensive injury than what leads to polymicrogyria. In most cases, the cause cannot be determined, but it has been associated with in utero insult. A rare familial form has been described, but no gene has been identified. Clinical features include developmental delay, cerebral palsy, dysarthria, and epilepsy. The clinical abnormalities are more severe with large open-lip schizencephaly and with bilateral lesions than with small unilateral closed-lip schizencephaly. Diagnosis is made by brain MRI. Management consists of seizure control and supportive therapies when indicated.

Malformations of Cerebellum and Brain Stem

Developmental abnormalities of the hindbrain are less well understood than are abnormalities of cerebral cortical development. Two of the better known and important syndromes are Joubert's syndrome and Dandy-Walker malformation.

JOUBERT'S SYNDROME

Joubert's syndrome is characterized by a distinctive pattern of cerebellar and brain stem developmental malformation. Four causative genes (*NPHP1*, *CEP290*, *AHI1*, and *TMEM67* [*MKS3*]) together account for approximately 30% of cases. Clinical features include hypotonia, truncal ataxia, developmental delay, abnormal eye movements, and disordered breathing. The combination of signs and severity can be variable. Some individuals with Joubert's syndrome also have retinal dystrophy, renal disease, ocular colobomas, occipital encephalocele, or hepatic fibrosis. No formal diagnostic criteria exist. The diagnosis is usually based on the combination of hypotonia in infancy with later development of ataxia, intellectual impairment, and abnormal breathing pattern, or abnormal eye movements in combination with a characteristic MRI finding known as the molar tooth sign. The molar tooth sign results from hypoplasia of the cerebellar vermis and accompanying brain stem abnormalities on axial imaging through the junction of the midbrain and pons. Genetic testing is available for the four identified genes. Management is supportive. Caffeine can be helpful for periodic hypoventilation, but some patients require tracheostomy.

DANDY-WALKER MALFORMATION

Dandy-Walker malformation is characterized by cerebellar vermis hypoplasia and cystic dilation of the fourth ventricle. Rare familial cases have been reported, but a genetic basis has not been identified. This heterogeneous disorder is usually accompanied by hypotonia, delayed motor development, and ataxia. Intellectual disability is present in about 50% of affected individuals. In some cases, hydrocephalus requires shunting. Diagnosis is based on characteristic findings on brain MRI. Treatment is supportive, with cerebrospinal fluid (CSF) shunting when indicated.

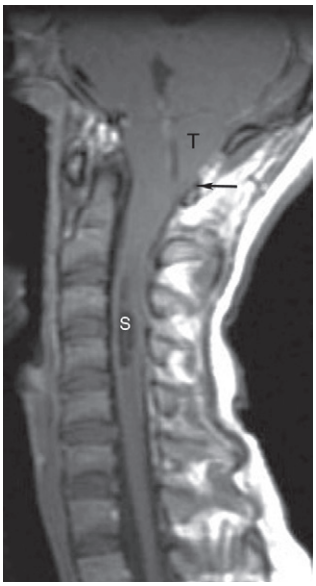

FIGURE 426-1. Chiari I malformation. A sagittal magnetic resonance image shows low, pointed cerebellar tonsils (i.e., Chiari I malformation, T) that extend to the level of C1 (*black arrow*) and a dilated central canal of the spinal cord (i.e., syringohydromyelia, S). (From Barkovich AJ, Kuzniecky RI. Congenital, Developmental, and Neurocutaneous Disorders. In Goldman L, Ausiello D, eds. *Cecil Textbook of Medicine,* 23rd ed. Philadelphia: Saunders Elsevier; 2008:2790.)

CHIARI MALFORMATIONS

Four types of Chiari malformation have been described. The most common of these are Chiari types I and II. Chiari I malformations are most often diagnosed in adulthood, whereas Chiari II malformations are associated with spina bifida and are usually diagnosed in childhood.

Chiari I malformations are characterized by downward displacement of the cerebellar tonsils through the foramen magnum, often first accompanied by compression of the tonsils. Chiari I is a developmental abnormality that is thought to be congenital in most cases, even though symptoms may not present until adulthood, typically in the third or fourth decade of life. The abnormality is often asymptomatic and discovered only as an incidental finding. However, clinical manifestations can result from compression of neural structures at the cranial-cervical junction or obstruction of CSF flow. Signs and symptoms include headaches that worsen with straining or coughing, lower cranial nerve findings, downbeat nystagmus, ataxia, or long-tract signs. Chiari I malformations are accompanied by syringomyelia (see later) in up to 80% of cases. Diagnosis is made with brain MRI, which shows the cerebellar tonsils extending through the foramen magnum 5 mm or more (Fig. 426-1). Surgical treatment with craniocervical decompression is recommended for symptomatic patients but usually not for asymptomatic individuals or patients whose only symptom is headache.

Chiari II malformations, commonly called Arnold-Chiari malformations, are characterized by descent of the cerebellar tonsils, the inferior vermis, and portions of the cerebellar hemispheres into the spinal canal along with elongation and displacement of the brain stem and fourth ventricle. Chiari II malformations are almost always associated with meningomyelocele and spina bifida. Hydrocephalus requiring shunting occurs in most cases. Brain stem dysfunction may result from intrinsic malformation or from compression of neural structures at the craniocervical junction. Treatment is surgical repair of the myelomeningocele, relief of hydrocephalus, and occasionally, cervical bone decompression. The prognosis depends on the level and extent of the myelomeningocele and on the severity of brain anomalies.

Malformations of Spinal Cord

Tethered Spinal Cord

Tethered spinal cord syndrome is a disorder caused by an anomalous filum terminale that restricts the normal ascent of the conus medullaris and limits the movement of the spinal cord within the spinal column. The result is an abnormal stretching of the spinal cord with neurologic symptoms referable to the lower spinal cord. Tethering may also develop after spinal cord injury. Associated spinal anomalies are common and may include diastematomyelia, spinal lipomas, dermal sinuses, and fibrolipomas of the filum terminale. Symptoms can occur at any age but usually develop during periods of rapid growth in childhood or adolescence. However, tethered spinal cord syndrome may go undiagnosed until adulthood, when sensory and motor problems and loss of bowel and bladder control emerge. Erectile dysfunction may occur in males. Symptoms are typically progressive. Diagnosis is made with MRI, which shows a low conus medullaris (i.e., below the bottom of the L2 vertebral body) or a thickened or fat-containing filum terminale. Diminished pulsations of the spinal cord may also be seen. Treatment consists of surgical release of the tethered cord. With successful surgery, symptoms typically do not progress and may improve.

SYRINGOHYDROMYELIA

Syringohydromyelia is a condition in which the central canal of the spinal cord (hydromyelia) or the substance of the spinal cord (syringomyelia) is expanded by the accumulation of CSF. In many cases, both hydromyelia and syringomyelia are present (syringohydromyelia). The proximate cause of syringes probably is altered flow of CSF with variations in pressure in different parts of the subarachnoid space. The pressure variations create forces that drive CSF into the spinal cord. Possible causes include narrowing of the foramen magnum, Chiari I and II malformations, intramedullary and extramedullary spinal cord tumors, and subarachnoid scarring. Subsequent extension of the cyst may result from rapid changes in intraspinal pressure owing to such events as coughing or sneezing. Symptoms of syringohydromyelia most commonly begin in late adolescence or early adulthood and progress irregularly, with long periods of stability. The classic presentation is asymmetrical weakness and atrophy in the upper extremities, loss of upper limb deep tendon reflexes, and loss of pain and temperature sensation (with preservation of vibration and proprioception) in the neck, arms, and upper part of the trunk. With progression, spasticity and hyperreflexia develop in the lower extremities. Progressive ascending and descending levels of weakness and sensory impairment typically occur over time. The diagnosis is made by spinal MRI (see Fig. 426-1). If syringohydromyelia is identified, it is important to perform a brain MRI to look for associated abnormalities of the craniocervical junction. Occasionally, mild central canal dilation is discovered incidentally in patients without spinal cord symptoms or signs. If no associated cause is found, the prognosis of such incidentally discovered anomalies is generally good. Treatment is directed at the cause, if one can be identified. Syringopleural or syringoperitoneal shunting is sometimes performed with variable benefit.

DEVELOPMENTAL DISORDERS

Disorders that result from impaired postnatal neurodevelopmental function range from specific disorders such as fragile X syndrome and Rett's syndrome, to complex syndromes such as autism, to nonspecific developmental delay and learning disabilities.

Fragile X Syndrome

Fragile X syndrome is an X-linked trinucleotide repeat disorder that is characterized by nonsyndromic mental retardation in most affected males. The pathogenesis of fragile X syndrome is not well understood. The classic disorder is seen in males with full mutations (>200 repeats) in the *FMR1* gene. Fragile X syndrome may present as only moderate to severe mental retardation, but it is often associated with a prominent forehead, large ears, prominent jaw, and macro-orchidism. Postpubertal males often have poor impulse control, perseveration, and poor eye contact. Up to 25% of affected males have autism. Heterozygous females may be asymptomatic or may have a syndrome similar to what is seen in males, depending on repeat size and random X-inactivation.

Other disorders associated with *FMR1* include the fragile X ataxia syndrome, which is characterized by the late onset, usually after age 50 years, of progressive cerebellar ataxia and intention tremor in individuals who have an *FMR1* premutation (60 to 200 repeats). It occurs equally in males and females. Diagnosis is by molecular genetic testing. Cytogenetic testing for fragile sites is no longer recommended because it is less sensitive and more expensive than molecular testing. Treatment is symptomatic and supportive. Genetic counseling is recommended for affected individuals and their families.

Rett's Syndrome

Rett's syndrome is a neurodevelopmental disorder that occurs in females with mutations in the *MECP2* gene. *MECP2* mutations are generally lethal in male embryos, but Rett's syndrome has been reported in males with XXY karyotype or with somatic mosaicism. *MECP2* is thought to mediate

transcriptional silencing of methylated DNA. Most mutations are probably de novo or may reflect germline mosaicism; 99% of cases represent a single occurrence within a family. Affected girls are usually normal at birth and have apparently normal development for the first 6 to 18 months of life. Brain growth decelerates, and development stagnates, followed by rapid regression of language and motor skills. A classic feature of Rett's syndrome is the loss of purposeful hand use and the development of repetitive stereotyped hand movements that usually have the appearance of wringing or clapping. Other features present to variable degree are bruxism, episodic apnea and hyperpnea, seizures, gait disorders, and tremor. Non-neurologic features include growth failure and wasting, bowel dysmotility, scoliosis, osteopenia, and vasomotor changes in the limbs. Diagnosis is by molecular genetic methods. Treatment is symptomatic.

Autism

Autism is a neurodevelopmental syndrome characterized by impaired communication, impaired social interaction, and restricted interests or repetitive behaviors. Fragile X syndrome and tuberous sclerosis are two important entities in which an autistic phenotype can occur and in which autism may be the most prominent feature. Symptoms typically present before 3 years of age and persist into adulthood. Autism is a spectrum ranging from severe, with impairment in all domains, to mild with normal intellect and language but with impaired social interactions and repetitive behaviors or restricted interests. Autism has many causes but in most cases is idiopathic. Epilepsy is common in autism. Diagnosis is based on careful diagnostic interview and examination. When epilepsy is present, treatment with antiepileptic medications is indicated. Behavioral therapy can help individuals learn rules for social interaction and can improve communication. It can also help with problematic behavior. Educational support is important. Medications such as atypical antipsychotics, selective serotonin reuptake inhibitors, and anxiolytics (Chapter 404) can help with aggressive behavior, repetitive behaviors, and anxiety.

NEUROCUTANEOUS DISORDERS

Neurocutaneous disorders are congenital syndromes characterized by dysplastic and neoplastic lesions primarily involving the nervous system and skin. The more than 40 described syndromes include neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome, and von Hippel-Lindau disease.

Neurofibromatosis

Neurofibromatosis encompasses a spectrum of syndromes with distinctive neural and cutaneous lesions. The two major forms of neurofibromatosis are genetically and clinically distinct.

NEUROFIBROMATOSIS TYPE 1

Neurofibromatosis type 1, which is the classic disorder described by von Recklinghausen, is an autosomal dominant condition with an incidence of 1 per 2500 to 3000 births. Although it is an autosomal dominant disease, approximately 50% of cases are due to new mutations. Most mutations in *NF1* occur in the parental germline. The *NF1* gene, which is located on chromosome 17q11.2, codes a protein called neurofibromin, which is thought to function as a tumor suppressor by acting as a negative regulator of the Ras signaling pathway. Neurofibromatosis type 1 is characterized by multiple cafe au lait spots, axillary and inguinal freckling, multiple discrete cutaneous neurofibromas (Fig. 426-2), and Lisch nodules (Table 426-1). Subcutaneous neurofibromas may be painful or disfiguring. Learning disabilities are present in at least 50% of individuals. Other manifestations include plexiform neurofibromas, optic nerve and other central nervous system (CNS) gliomas, malignant peripheral nerve sheath tumors, tibial dysplasia, and vasculopathy.

Management of patients depends on the specific manifestations and often requires multidisciplinary collaboration. Most patients with neurofibromatosis type 1 do not require treatment, but all require surveillance (Table 426-2). Subcutaneous, intraspinal, and intracranial tumors can be treated surgically. Optic nerve gliomas may be treated with chemotherapy; both cisplatin and temozolomide have shown some benefit. Radiation is not recommended. Genetic counseling should be provided to all patients and their families.

NEUROFIBROMATOSIS TYPE 2

Neurofibromatosis type 2, which is often referred to as central neurofibromatosis, is an autosomal dominant condition with an incidence of approximately 1 in 25,000 individuals. The *NF2* gene is located on chromosome 22q12.2. Its gene product, merlin, is cytoskeletal protein that is thought to act as a membrane-stabilizing protein. The specific function of merlin is unknown. Neurofibromatosis type 2 is characterized by bilateral vestibular schwannomas, which usually present with symptoms of tinnitus, hearing loss, and imbalance. The age at onset is usually in young adulthood, but some individuals may develop posterior subcapsular lens opacities or mono-neuropathy in childhood. Almost all affected individuals develop bilateral vestibular schwannomas by age 30 years (Table 426-3). Affected individuals may also develop schwannomas of other cranial and peripheral nerves, meningiomas, and, rarely, ependymomas or astrocytomas. Posterior subcapsular lens opacities are the most common ocular abnormality.

Management is dependent on the specific manifestations and complications. In individuals who either have tested positive for known *NF2* mutations or have a family history of neurofibromatosis type 2 and whose genetic status cannot be determined with genetic testing, annual brain MRI is recommended starting between ages 10 and 12 years and continuing until at least age 40 years. Hearing evaluations may be useful in detecting changes in auditory nerve function before changes can be visualized by MRI. Routine complete eye examinations should be part of the care of all individuals.

Bevacizumab, a vascular endothelial growth factor inhibitor (5 mg/kg intravenously every 2 weeks), can improve hearing in some patients with neurofibromatosis type 2 and vestibular schwannomas.■ Surgical treatment of schwannomas and meningiomas may be indicated to preserve function or to relieve compression of adjacent structures, especially in patients with intramedullary spinal tumors. Genetic counseling should be provided to affected individuals and their families.

FIGURE 426-2. Multiple neurofibromas covering the back of a patient with neurofibromatosis type 1.

TABLE 426-1 DIAGNOSTIC CRITERIA FOR NEUROFIBROMATOSIS TYPE 1

Two or more of the following clinical features signify the presence of neurofibromatosis type 1:
Six or more cafe au lait macules (>0.5 cm at largest diameter in prepubertal individuals or >1.5 cm in individuals past puberty)
Axillary freckling or freckling in inguinal regions
Two or more neurofibromas of any type or ≥1 plexiform neurofibroma
Two or more Lisch nodules (iris hamartomas)
A distinctive osseous lesion
A first-degree relative with neurofibromatosis type 1 diagnosed by using the above-listed criteria

TABLE 426-2 RECOMMENDED SURVEILLANCE IN PATIENTS WITH NEUROFIBROMATOSIS TYPE 1

Annual physical examination by a physician who is familiar with the individual and with the disease
Annual ophthalmologic examination in early childhood, less frequent examination in older children and adults
Regular developmental assessment by screening questionnaire (in childhood)
Regular blood pressure monitoring
Other studies only as indicated on the basis of clinically apparent signs or symptoms
Monitoring of those who have abnormalities of the central nervous system, skeletal system, or cardiovascular system by an appropriate specialist

TABLE 426-3 DIAGNOSTIC CRITERIA FOR NEUROFIBROMATOSIS TYPE 2

Presence of one or more of the following makes the diagnosis of neurofibromatosis type 2:

- Bilateral vestibular schwannomas
- A first-degree relative with neurofibromatosis type 2, *and*
  - Unilateral vestibular schwannoma, *or*
  - Any two of: meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities*
- Unilateral vestibular schwannoma, *and*
  - Any two of: meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities*
- Multiple meningiomas, *and*
  - Unilateral vestibular schwannoma, *or*
  - Any two of: schwannoma, glioma, neurofibroma, cataract*

*"Any two of" refers to two individual tumors or cataracts.

TABLE 426-4 DIAGNOSTIC CRITERIA FOR TUBEROUS SCLEROSIS COMPLEX

Definite—Two major features or one major feature plus two minor features
Probable—One major feature plus one minor feature
Possible—One major feature or two or more minor features

Major features
- Facial angiofibromas or forehead plaque
- Nontraumatic ungual or periungual fibromas
- More than three hypomelanotic macules (ash leaf spots)
- Shagreen patch (connective tissue nevus)
- Multiple retinal nodular hamartomas
- Cortical tuber
- Subependymal nodule
- Subependymal giant cell astrocytoma
- Cardiac rhabdomyoma, single or multiple
- Lymphangiomyomatosis
- Renal angiomyolipoma

Minor features
- Multiple dental enamel pits
- Hamartomatous rectal polyps
- Bone cysts
- Cerebral white matter radial migration lines
- Gingival fibromas
- Nonrenal hamartoma
- Retinal achromic patch
- "Confetti" skin lesions
- Multiple renal cysts

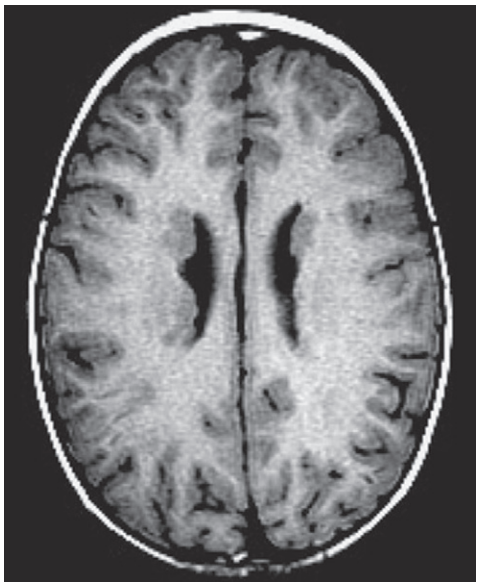

FIGURE 426-3. Subependymal nodules and multiple cortical tubers in a patient with tuberous sclerosis.

FIGURE 426-4. Sturge-Weber syndrome. This patient has a classic diffuse capillary hemangioma in the distribution of the ophthalmic, nasociliary, and maxillary branches of the trigeminal nerve. The lesion extends backward over the anterior two thirds of the crown of the head. (From Forbes CD, Jackson WD. *Color Atlas and Text of Clinical Medicine*, 2nd ed. London: Mosby; 1996.)

Tuberous Sclerosis

Tuberous sclerosis complex is characterized by abnormalities of the brain, kidney, and heart. Tuberous sclerosis may occur as an autosomal dominant syndrome or result from spontaneous mutation. Two tuberous sclerosis genes have been identified. *TSC1* (chromosome 9q34) codes for a protein called hamartin, a protein that interacts with the product of the *TSC2* gene to inhibit the mammalian target of rapamycin (mTOR). *TSC2* (chromosome 16p13) codes for tuberin, which interacts with hamartin. *TSC2* mutations account for about 60% of individuals with clinical tuberous sclerosis.

The specific findings vary across individuals, and severity ranges from minimal to severe. Skin lesions are seen in almost 100% of affected individuals, but CNS lesions are the leading cause of morbidity and mortality. Epilepsy is seen in as many as 80% of patients with CNS lesions. Intellectual impairment and developmental delay are common, and up to 40% of patients have an autism spectrum disorder. Giant cell astrocytoma is the leading cause of death. Up to 80% of children with tuberous sclerosis have an identifiable renal lesion (Chapter 203) by 10.5 years of age, and renal disease is the second leading cause of early death in individuals with tuberous sclerosis. Cardiac rhabdomyomas, which can occur in up to 50% of patients, are usually present at birth and typically regress over time. Diagnosis of tuberous sclerosis (Table 426-4) is usually clinical and confirmed by identification of calcified or uncalcified hamartomas on imaging studies (Fig. 426-3).

Treatment is directed at complications of the disease, particularly epilepsy (Chapter 410). Neurosurgical intervention may sometimes be indicated for epilepsy and for symptomatic treatment of complications, such as hydrocephalus, which results from midline giant cell tumors. In a small, nonrandomized study, treatment with sirolimus (dosed to achieve blood levels of 1 to 5 ng/mL) for 1 year reduced the size of the angiomyolipomas during the year of treatment. Rapamycin has shown promise in early investigations for treatment of giant cell astrocytomas. Serial brain MRI and renal ultrasound screening may be indicated in some patients because benign tumors of these organs may enlarge rapidly. Genetic counseling is an important part of management.

Sturge-Weber Syndrome

Sturge-Weber syndrome is a sporadic disorder characterized by facial vascular nevi, epilepsy, cognitive impairment, and sometimes hemiparesis, hemianopsia, or glaucoma. The characteristic CNS feature of this disorder is capillary angiomatosis of the pia mater. Cerebral cortical calcifications are generally seen in a pericapillary distribution and are progressive. Most patients with Sturge-Weber syndrome have epilepsy. The diagnosis is usually based on the presence of a facial nevus (Fig. 426-4), which is manifested as a typical port-wine stain, and confirmatory imaging on a contrast brain MRI showing leptomeningeal enhancement.

Regular ophthalmologic examination is warranted because of the risk for glaucoma. Treatment is usually aimed at the epilepsy, which can be medically

intractable. In patients with intractable epilepsy and infantile-onset hemiplegia, hemispherectomy can improve the seizures and the neurodevelopmental outcome.

Von Hippel-Lindau Disease

Von Hippel-Lindau disease (i.e., CNS angiomatosis) is an autosomal dominant disorder caused by a defective tumor suppressor gene at chromosome 3p25-p26. It is characterized by retinal angiomas, brain (usually cerebellar) and spinal cord hemangioblastomas, renal cell carcinomas, endolymphatic sac tumors, pheochromocytomas, papillary cystadenomas of the epididymis, angiomas of the liver and kidney, and cysts of the pancreas, kidney, liver, and epididymis. Both sexes are affected equally.

Symptoms typically begin during the third or fourth decade. Retinal inflammation with exudate, hemorrhage, and retinal detachment from the retinal angiomas typically precedes the cerebellar complaints, but the order is not constant. The ocular findings are nonspecific, and the retinal detachment may mask the underlying lesion. Headache, vertigo, and vomiting result from cerebellar tumors. Cerebellar signs such as ataxia, dysdiadochokinesis, and dysmetria are common. Rare patients present with symptoms of spinal cord or visceral lesions, or may have hearing loss from tumors of the endolymphatic sac.

Clinical diagnosis is established if the patient has more than one CNS hemangioblastoma, one hemangioblastoma with a visceral manifestation of the disease, or one manifestation of the disease and a known family history. Molecular genetic testing detects mutations in the *VHL* gene in nearly 100% of affected individuals.

For patients with von Hippel-Lindau disease and for those with a disease-causing VHL mutation, surveillance is recommended with annual ophthalmologic examination, annual blood pressure monitoring, measurement of urinary catecholamine metabolites beginning at age 5 years in families with pheochromocytoma, and annual abdominal ultrasound examination beginning at age 16 years with evaluation of suspicious lesions by computed tomography or MRI. Treatment is symptomatic. Retinal detachments and tumors are treated by laser therapy. Large brain tumors (Chapter 195), renal cell carcinomas (Chapter 203), pheochromocytomas (Chapter 235), epididymal tumors (Chapter 206), and endolymphatic sac tumors are treated surgically; smaller CNS tumors may be treated by gamma knife.

AUTONOMIC DISORDERS AND THEIR MANAGEMENT

WILLIAM P. CHESHIRE, JR.

The peripheral autonomic nervous system and the central integration of autonomic reflexes maintain homeostasis and modulate the complex physiologic responses at the interface between the internal milieu and the external world. Autonomic activity, which generally occurs below the level of conscious control, regulates cardiovascular, thermal, metabolic, gastrointestinal, urinary, and reproductive functions and coordinates the adaptive response to stress.

Many diseases can involve the autonomic nervous system, which in turn can involve all organ systems. Examples include brain lesions that affect any part of the central autonomic network, disorders that damage peripheral nerve function, and systemic illnesses that impair autonomic responses.

EPIDEMIOLOGY

The most frequently disabling manifestation of autonomic failure is orthostatic hypotension, which increases in prevalence with aging and is associated with a two-fold increased risk for falls, fractures, syncope, transient ischemic attacks, and decreased functional capacity in elderly individuals. The prevalence of orthostatic hypotension is 5 to 20% among all elderly persons, but it rises to 30% in persons older than 75 years and to greater than 50% in frail individuals who live in nursing homes. Neurally mediated syncope (vasodepressor, vasovagal), as well as various situational syncopes that occur in response to emotional distress, micturition, defecation, coughing, carotid sinus stimulation, and other factors, accounts for 1 to 3% of all emergency room visits. The lifetime prevalence of syncope is about 20%. Another common autonomic syndrome is postprandial hypotension, which occurs in 20 to 60% of elderly individuals and increases the risk for mortality by 80%.

Diabetes mellitus (Chapter 236) is the most common cause of autonomic neuropathy in the developed world. Within 10 to 15 years of the onset of diabetes, laboratory evidence of autonomic neuropathy can be detected in about 30% of patients, and symptomatic autonomic failure with orthostatic hypotension can be detected in about 5% of patients. Other autonomic symptoms in diabetics include constipation in 40 to 60% of patients, gastroparesis in 20 to 40%, bladder dysfunction in 30 to 80%, erectile impotence in more than 30% of males, and occasionally, intermittent diarrhea.

Hyperhidrosis involving the palms and soles represents the most common form of essential hyperhidrosis and affects about 1% of the population. Although excessive sweating is usually symptomatic, anhidrosis may go unnoticed unless it interferes with the thermoregulatory response to heat stress. Impaired thermoregulation can cause increased mortality rates during heat waves or in times of heat stress (Chapter 109).

PATHOBIOLOGY

The peripheral autonomic nervous system comprises three main divisions: (1) *sympathetic*, or outflow from the thoracolumbar segments of the spinal cord; (2) *parasympathetic*, or outflow from cranial nerves III, VII, IX, and X and from the sacral spinal segments; and (3) *enteric*, or the ganglionated plexuses intrinsic to the wall of the gut. Disorders of the autonomic nervous system may occur suddenly or evolve gradually. They may affect specific or multiple autonomic pathways depending on their pathogenesis and localization. Orthostatic hypotension, a hallmark of autonomic disorders, results from sympathetic vasomotor denervation, which renders a standing patient unable to constrict the splanchnic and other peripheral vascular beds in response to the pooling of blood volume (500 to 1000 mL) secondary to gravity.

Physiologic effects of sympathetic activation include pupillary dilation, increased heart rate and contractility, increased peripheral vascular resistance, bronchodilation, increased glandular secretions, decreased gastrointestinal motility, increased sweating, decreased function of reproductive organs, and mobilization of energy substrates. The effects of parasympathetic activation include pupillary constriction, lacrimal and salivary secretion, decreased heart rate and contractility, bronchoconstriction, increased gastrointestinal motility, and contraction of the detrusor muscle of the bladder. Sympathetic and parasympathetic responses, though generally antagonistic, are not always equally counterbalanced.

Sympathetic preganglionic neurons, which use acetylcholine as their primary neurotransmitter, originate in the segmentally organized intermediolateral column of the spinal cord and exit via the ventral roots to pass through the white rami communicans and reach the paravertebral sympathetic chain ganglia, which innervate all organs and tissues except those of the abdomen and pelvis. The superior cervical ganglion, for example, innervates cranial structures, and the stellate ganglion innervates the upper limb. Sympathetic preganglionic axons also form the splanchnic nerves, which innervate the celiac, superior mesenteric, and hypogastric ganglia, as well as the adrenal medulla. With the exception of neurons that innervate the sweat glands, which are cholinergic, all other sympathetic postganglionic neurons are adrenergic and use norepinephrine as their primary transmitter.

Preganglionic innervation of parasympathetic neurons is also cholinergic; however, in contrast to their sympathetic counterparts, the major postganglionic parasympathetic neurotransmitter is acetylcholine. Parasympathetic preganglionic fibers originate in the Edinger-Westphal, salivatory, and vagal dorsal motor nuclei in the brain stem. The ciliary, sphenopalatine, otic, submandibular, sublingual, and pelvic ganglia send postganglionic parasympathetic fibers to their target organs. Cranial nerves IX and X, which constitute the afferent limbs of the baroreceptor reflex, relay beat-to-beat information about systemic arterial pressure to the nucleus of the solitary tract.

The gastrointestinal tract contains neural plexuses, the most prominent of which are the myenteric (Auerbach) plexus found between the two layers of the muscularis externa and the submucosal (Meissner) plexus. Disorders of the enteric nervous system mainly affect gastrointestinal motility or sphincter control rather than absorptive or secretory functions.

BRAIN DISORDERS

Important disease targets involved in central autonomic regulation include the interrelated neuronal cell groups of the hypothalamus, as well as the ventrolateral medulla, nucleus of the solitary tract, parabrachial nucleus, periaqueductal gray matter, amygdala, and insular and prefrontal cortices. Together, these relay systems and integrative centers compose the central autonomic network, which when impaired, fails to activate or modulate sympathetic and parasympathetic tone and neurohumoral responses.

A number of neurodegenerative disorders disrupt the central pathways of autonomic regulation. The most severe form is multiple system atrophy, a sporadic, adult-onset disease in which severe autonomic failure accompanies and occasionally precedes parkinsonism (Shy-Drager syndrome; Chapter 416) or cerebellar ataxia (Chapter 417). In multiple system atrophy, there is degeneration of the striatum, pigmented nuclei, pontine nuclei, inferior olives, cerebellar Purkinje cells, and dorsal vagal and vestibular nuclei. Autonomic dysfunction also occurs in dementia with Lewy bodies (Chapter 409) and, to a lesser degree, in Parkinson's disease, both of which also involve abnormal neuronal accumulation of α-synuclein.

Essential to the integration of behavioral, autonomic, and neuroendocrine responses is the tightly packed, interwoven group of cells that constitute the hypothalamus. Lesions of the anterior hypothalamus may alter thirst perception and sodium regulation. Dysfunction of the magnocellular arginine vasopressin neurons of the supraoptic and supraventricular nuclei can be manifested as decreased secretion of antidiuretic hormone, thereby resulting in diabetes insipidus (Chapter 232) with hypovolemia, or as inappropriately increased secretion of antidiuretic hormone, thereby resulting in hyponatremia. Medial preoptic–anterior hypothalamic dysfunction associated with dysgenesis of the corpus callosum (Shapiro's syndrome) is characterized by episodic hyperhidrosis and hypothermia. Lesions of the posterior hypothalamus can result from hypothermia, Wernicke-Korsakoff syndrome (Chapter 425), acute traumatic brain injury (Chapter 406), multiple sclerosis (Chapter 419), mesodiencephalic hematoma, and toluene toxicity.

Catastrophic neurologic conditions such as subarachnoid hemorrhage, head trauma, status epilepticus, and acute hydrocephalus with increased intracranial pressure can profoundly stimulate sympathetic responses with cardiovascular consequence. Release of the hypothalamus as a result of cortical inhibition is the presumed mechanism. These paroxysmal sympathetic storms (diencephalic syndrome) are characterized by episodic sympathetic hyperactivity with hypertension, tachycardia, hyperventilation, pupillary dilation, flushing, and diaphoresis. Communicating hydrocephalus, structural lesions affecting the medial frontal cortex, and degenerative conditions affecting the frontobasal ganglia can cause urinary incontinence with uninhibited bladder contractions.

Autonomic responses are closely linked to emotional states. Portions of the insular and anterior cingulate cortices mediate the autonomic responses to emotional stress. Because cardioregulatory function is represented within the insular cortex, insular strokes have been associated with destabilization of sympathoregulatory balance and occasional adverse cardiac events. Correlations of electroencephalography and electrocardiography have shown that seizures arising from the mesial temporal lobe may induce ictal tachycardia or, more rarely, bradycardia or asystole.

Lesions of the brain stem may also be manifested as autonomic dysfunction. Damage to the medulla oblongata may give rise to hypertension, orthostatic hypotension, or syncope. Medullary ischemia or compression can cause acute neurogenic hypertension (Cushing's response). Lateral medullary infarction (Wallenberg's syndrome) typically produces ipsilateral Horner's syndrome and occasionally more extensive dysautonomia, including bradycardia, acute hypertension, supine hypotension, or central hypoventilation.

TABLE 427-1 SOME CAUSES OF PERIPHERAL AUTONOMIC NEUROPATHY

Metabolic	Diabetes mellitus Alcohol Acute intermittent porphyria Uremia
Autoimmune	Autoimmune autonomic ganglionopathy Guillain-Barré syndrome Morvan's syndrome Lambert-Eaton myasthenic syndrome Chronic inflammatory demyelinating polyradiculoneuropathy Sjögren's syndrome Systemic lupus erythematosus Mixed connective tissue diseases
Paraproteinemic	Amyloidosis
Nutritional	Cyanocobalamin deficiency Thiamine deficiency Gluten-sensitive neuropathy
Toxic	Heavy metals Organic solvents Organophosphates Vacor Acrylamide
Drug induced	Cisplatin Vincristine Amiodarone Metronidazole Perhexiline Paclitaxel
Infectious	Human immunodeficiency virus Leprosy Chagas' disease Botulism Diphtheria Lyme disease
Genetic	Hereditary sensory and autonomic neuropathies Types I and II Type III (familial dysautonomia) Type IV (congenital insensitivity to pain) Type V Fabry's disease
Idiopathic	Adie's syndrome Ross' syndrome Acute cholinergic neuropathy Chronic idiopathic anhidrosis Amyotrophic lateral sclerosis

SPINAL CORD DISORDERS

Lesions of the spinal cord, whether compressive, demyelinating, vascular, or neoplastic, commonly result in an overactive bladder (Chapter 25) with symptoms of frequency, urgency, and sometimes incontinence. Lesions that involve the sacral cord segments or cauda equina result in an underactive bladder with incomplete emptying, overflow incontinence, sphincter atonia, and sexual dysfunction.

After spinal cord injuries above the level of T5, sprouting of afferent fibers in the thoracolumbar dorsal horns and necrosis of the descending white matter connections to sympathetic preganglionic neurons result in autonomic dysreflexia. In these patients, peripheral sensory stimuli such as bladder distention can induce a reversible state of sympathetic hyperresponsiveness, including hypertension, diaphoresis, flushing, and headache.

PERIPHERAL GANGLIONOPATHIES AND NEUROPATHIES

Autonomic dysfunction can arise at the level of the autonomic ganglia or peripheral nerves (Table 427-1). Peripheral autonomic nerves are generally small in caliber and unmyelinated or thinly myelinated. Peripheral neuropathies selectively involve small nerve fibers and cause various combinations of sensory, sympathetic, or parasympathetic signs and symptoms.

TABLE 427-2 AUTOIMMUNE AUTONOMIC NEUROPATHIES

CLINICAL SYNDROME	ASSOCIATED AUTOANTIBODY
Autoimmune autonomic ganglionopathy	Anti-GAChR
Guillain-Barré syndrome	Anti-GM_1, anti-GM_3
Paraneoplastic autonomic neuropathy	ANNA-1 (anti-Hu), PCA-2, CRMP-5
Lambert-Eaton myasthenic syndrome	Anti-VGCC
Morvan's syndrome	Anti-VGKC
Sjögren's syndrome	SSA (anti-Ro), SSB (anti-La)

ANNA-1 = antineuronal nuclear antibody; anti-GAChR = nicotinic ganglionic acetylcholine receptor antibody; anti-GM_1, anti-GM_3 = antiganglioside antibody; anti-VGCC = P/Q-type voltage-gated calcium-channel antibody; anti-VGKC = voltage-gated potassium-channel antibody; CRMP-5 = collapsin response mediator protein 5; PCA-2 = Purkinje cell cytoplasmic antibody type 2.

Among the peripheral dysautonomias is the syndrome of pure autonomic failure, which is defined as the insidious onset of severe, generalized autonomic failure as the sole clinical feature in the absence of any signs of extrapyramidal, cerebellar, or sensory or motor peripheral nerve dysfunction. Pathologic studies have found Lewy body accumulation in autonomic ganglia, peripheral autonomic nerves, the substantia nigra, and the locus ceruleus.

Diabetic neuropathy involves autonomic nerves early in its course but advances to clinically apparent autonomic neuropathy only in about 14% of patients. The incidence increases with the duration of diabetes and advancing age. In diabetic patients, microvascular ischemia causes progressive peripheral nerve damage, although an autoimmune mechanism may also play a role in a subset of patients. Some patients with otherwise unexplained distal small fiber autonomic neuropathy have impaired fasting glucose. Whether this association reflects an early stage of diabetic neuropathy or a chance association, given the prevalence of glucose intolerance, remains to be determined.

Other syndromes of neurologic autoimmunity (Table 427-2) include Guillain-Barré syndrome, in which antiganglioside antibodies mediate an acute inflammatory demyelinating polyradiculoneuropathy that may be associated with tachycardia, blood pressure lability, and pupillomotor, sudomotor, and vasomotor disturbances (Chapter 428). The syndrome of acute pandysautonomia is typically manifested dramatically over a period of days to weeks as combined sympathetic and parasympathetic failure with gastrointestinal dysmotility and, in contrast to Guillain-Barré syndrome, sparing of the somatic nerves. An antecedent, presumably viral infection is reported in about 50% of cases. The finding of antibodies against the nicotinic acetylcholine receptor in the autonomic ganglia in many of these patients has led to the clinical designation autoimmune autonomic ganglionopathy. Ganglionic acetylcholine receptor antibodies occur in some patients with lung cancer or thymoma. Low levels of these antibodies have also been found in a subset of patients with isolated gastrointestinal dysmotility.

Autoimmune neuromyotonia is characterized by peripheral nerve hyperexcitability, insomnia, fluctuating delirium, and prominent dysautonomia with hyperhidrosis and orthostatic intolerance. Most patients have antibodies to voltage-gated potassium channels.

Paraneoplastic autonomic neuropathies (Chapter 187), which can predate the diagnosis of malignancy, are a rare epiphenomenon of malignancy, most frequently small cell lung carcinoma (Chapter 197), and can also occur in association with ovarian carcinoma (Chapter 205), breast carcinoma (Chapter 204), thymoma, lymphoma (Chapter 191), and other cancers. The most commonly encountered paraneoplastic antibody is antineuronal nuclear antibody type 1 (ANNA-1 or anti-Hu), which binds to a 35- to 40-kD family of neuronal nuclear RNA-binding proteins, including those in autonomic and enteric ganglia. Antibodies against collapsing response mediator proteins (CRMP-5 or anti-CV2) have also been associated with paraneoplastic autonomic neuropathy. Dysautonomia occurs in approximately 10 to 30% of patients with ANNA-1 and in 30% of patients with CRMP-5 seropositivity. Small cell lung cancer (Chapter 197) has been found in more than 80% of patients seropositive for ANNA-1 or CRMP-5.

Hereditary sensory and autonomic neuropathy (HSAN) type I, which is due to a mutation of the gene for serine palmitoyltransferase long-chain base subunit 1, is inherited in an autosomal dominant pattern and is characterized by distal anhidrosis with loss of nociceptive and thermal perception. Mutations in *HSN2* have been linked to HSAN type II, an autosomal recessive neuropathy that causes distal anhidrosis and sensory loss. Sural nerve biopsy specimens disclose virtual absence of myelinated fibers and decreased numbers of unmyelinated fibers. Autonomic involvement is most prominent in HSAN type III, commonly known as familial dysautonomia, or Riley-Day syndrome. This autosomal recessive disorder, which affects 1 in 3600 live births in parents of Ashkenazi Jewish descent, has been linked to mutations in the I-κB kinase–associated protein gene (*IKBKAP*). Pathologic studies disclose severely depleted sympathetic preganglionic and postganglionic neuronal populations with preservation of parasympathetic neurons. Affected children cry without tears, feed poorly, lack fungiform papillae, have depressed patellar reflexes, and are subject to orthostatic hypotension and autonomic storms.

HSAN type IV, or congenital insensitivity to pain with anhidrosis, is an autosomal recessive disorder that is associated with mental retardation and repeated episodes of fever. HSAN type IV results from mutations in the gene for neurotrophic tyrosine kinase receptor type 1 (*NTRK1*), which is important for inducing neurite outgrowth in embryonic sensory and sympathetic neurons. Peripheral nerve biopsy discloses virtual absence of unmyelinated fibers.

HSAN type V is an autosomal recessive disorder characterized by loss of pain sensation and sudomotor abnormalities.

The age-related decline in baroreflex sensitivity, adrenergic responses to sympathetic activation, parasympathetic control of heart rate, esophageal and gastrointestinal motility, and efficient thermoregulation predisposes the elderly to orthostatic, postprandial, and drug-induced hypotension. Pheochromocytomas (Chapter 235) and carcinoid syndrome (Chapter 240) can also be accompanied by autonomic symptoms, including blood pressure lability.

CLINICAL MANIFESTATIONS

Several common patterns of autonomic dysfunction may be distinguished.

Generalized Autonomic Failure

Early symptoms of adrenergic failure typically include lightheadedness on arising in the morning or following a warm shower, physical exercise, or a large meal. Other common symptoms include male erectile dysfunction, decreased sweating, dry mouth, constipation, and bladder dysfunction. Severe orthostatic hypotension without pulse acceleration, which is the hallmark of severe generalized autonomic failure, may be accompanied by supine and nocturnal hypertension, thus reversing the normal diurnal decrease in blood pressure during sleep.

Acute Autonomic Syndromes

Acute or subacute manifestations of autonomic dysfunction may result from rapidly developing disease or from decompensation of chronic autonomic disease. An abrupt onset of new focal autonomic signs, particularly when accompanied by headache or motor or sensory deficits, should prompt a detailed neurologic assessment for an acute cerebral or spinal syndrome, which may be caused by vascular, traumatic, inflammatory, neoplastic, or infectious diseases.

Chronic Autonomic Syndromes

The clinical spectrum of chronic autonomic neuropathies includes distal small fiber neuropathies with a stocking-and-glove distribution of anhidrosis, often combined with loss of pain and temperature sensibility. Other patients may have orthostatic hypotension and impaired exercise tolerance, with either an increased resting heart rate because of a parasympathetic cardiovagal neuropathy or a fixed heart rate that does not increase adequately in response to physiologic demands as a result of the involvement of sympathetic fibers. Some patients with distal sudomotor neuropathy will complain of spontaneous or gustatory proximal hyperhidrosis with episodic sweating involving the face, head, and upper part of the trunk.

Gastroparesis, which is a common feature of autonomic neuropathies, is characterized by delayed gastric emptying, which may be manifested as early satiety, nausea, anorexia, bloating, and sometimes pain and weight loss. Intestinal dysmotility may cause severe constipation (Chapter 138). In advanced peripheral neuropathies, in ganglionopathies in which involvement is not length dependent, and in central degenerative disorders, the loss of sweating may extend to proximal body regions or globally. Widespread anhidrosis may result in impaired thermoregulatory sweating and the potential for hyperthermia in conditions of heat stress (Chapter 109).

Paroxysmal Dysautonomias

Paroxysmal and episodic autonomic symptoms include postprandial hypotension, which is a reduction in systolic blood pressure of at least 20 mm Hg within 2 hours of the start of a meal, typically one high in carbohydrate content. Postprandial hypotension may occur in elderly individuals with or without orthostatic hypotension.

Dysfunction of the afferent limb of the baroreflex system leads to volatile blood pressure in patients with acute inflammatory demyelinating polyneuropathy and syndromes of baroreflex failure. Additional causes of aberrant activation of autonomic reflexes include epilepsy, diencephalic syndrome, subarachnoid hemorrhage, acute head trauma, pheochromocytoma, intoxication, drug withdrawal, neurally mediated syncope, and panic disorder.

Selective Autonomic Syndromes

Regional autonomic disorders are characterized by focal or system-selective autonomic dysfunction. An example is harlequin syndrome, in which heat stress, exercise, or sudden emotion in a patient with hemifacial cutaneous sympathetic denervation evokes a dramatic facial division in which the denervated half remains pale and dry and the intact half flushes red. Oculosympathetic paresis or Horner's syndrome may also be present. Harlequin syndrome may occur in patients with Holmes-Adie syndrome, which consists of tonic pupils with asymmetrical or absent tendon reflexes, and has been described in patients with Ross' syndrome, a partial dysautonomia consisting of the clinical triad of unilateral or bilateral tonic pupils, tendon hyporeflexia, and segmental body anhidrosis.

Other Specific Syndromes

Baroreflex failure is commonly the result of damage to the carotid sinus baroreceptors or the glossopharyngeal nerves. Similarly, interruption of vagal input from the aortic arch baroreceptors to the nucleus of the solitary tract can impair baroreflex responses. Baroreflex failure also occurs in patients who have undergone surgery or irradiation of the neck. These patients will exhibit severe and labile hypertension with concomitant tachycardia, palpitations, headache, diaphoresis, and emotional lability.

Serotonin syndrome develops within hours or days of the addition of a new serotonergic agent to a drug regimen that already enhances serotonergic neurotransmission, on overdose with a selective serotonin reuptake inhibitor, or from abuse of psychostimulants such as amphetamine, methamphetamine, and 3,4-methylenedioxymetamphetamine (MDMA or "ecstasy"). Manifestations include agitation, hypervigilance, confusion, hyperthermia, increased sweating, fluctuating blood pressure, hyperreflexia, and myoclonus.

Neuroleptic malignant syndrome (Chapters 440 and 442) is a potentially life-threatening hypermetabolic condition that develops within days to weeks in 0.2% of patients who receive drugs that block dopamine 2 receptors. The clinical findings consist of hyperthermia, profuse sweating, muscle rigidity, bradykinesia, and delirium. If the offending medication is not withheld, the syndrome may progress to tachycardia, tachypnea, labile blood pressure, myoclonus, obtundation, and catatonia.

Among the infectious neuropathies, tetanus infection (Chapter 304) causes sympathetic overactivity in a third of patients because of the exotoxin tetanospasmin, which is taken up by peripheral nerve terminals and transported across synaptic junctions to reach the central nervous system. There it binds to gangliosides at presynaptic junctions to disinhibit preganglionic neurons and damages autonomic brain stem nuclei. Sympathetic hyperactivity results in labile or persistent hypertension or hypotension, tachyarrhythmias, peripheral vasoconstriction, fever, and profuse sweating. Diphtheritic neuropathy (Chapter 300) causes bulbar weakness and may be associated with cardiovagal impairment but not usually with orthostatic hypotension.

The acute cholinergic neuropathy of botulism (Chapter 304) occurs along with bulbar and generalized neuromuscular paralysis 12 to 36 hours after the ingestion of food contaminated with the gram-positive anaerobic bacterium *Clostridium botulinum*. Botulinum toxin binds with high affinity to presynaptic receptors of cholinergic nerve terminals and inhibits the release of acetylcholine, thereby blocking neuromuscular and cholinergic autonomic transmission. Autonomic manifestations include anhidrosis, dry eyes, dry mouth, paralytic ileus, gastric dilation, urinary retention, and sometimes orthostatic hypotension with fluctuating blood pressure and vasomotor tone.

Human immunodeficiency virus infection commonly causes autonomic disturbances, particularly in its advanced stages. Manifestations can include orthostatic hypotension, tachycardia, urinary dysfunction, impotency, diarrhea, and cardiac conduction defects. Perivascular mononuclear inflammatory infiltrates and neuronal degeneration in biopsy specimens of sympathetic ganglia suggest an autoimmune pathogenesis.

TABLE 427-3 SOME COMMONLY PRESCRIBED DRUGS THAT AFFECT SWEATING

Drugs that increase sweating
Opioids
Serotonin re-uptake inhibitors
Anticholinesterases
Cholinergic agonists
Drugs that decrease sweating
M_3 anticholinergics
Carbonic anhydrase inhibitors
Tricyclic antidepressants
Neuroleptics
Antihistamines
Central α-adrenergic agonists
Botulinum toxin

Chagas' disease (Chapter 355) causes a predominantly parasympathetic neuropathy characterized by megaesophagus, megaduodenum, and megacolon, as well as sympathetic cardiovascular failure with cardiomegaly and conduction defects. The autonomic neuropathy has an autoimmune basis and develops years to decades following primary infection with *Trypanosoma cruzi*.

Leprosy (Chapter 334), one of the most common causes of neuropathy worldwide, frequently causes peripheral autonomic neuropathy as a result of an immune reaction against *Mycobacterium leprae*. Focal anhidrosis occurs in areas of hypopigmented and hypoesthetic skin. Cardiac denervation and orthostatic hypotension have been described.

Toxins known to cause autonomic neuropathy include the rodenticide Vacor, as well as thallium, arsenic, mercury, acrylamide, and organic solvents such as carbon disulfide and hexacarbon. Organophosphate poisoning (Chapter 110) induces miosis and copious secretions. Ergot poisoning from rye contaminated with the fungus *Claviceps purpurea* results in intense vasoconstriction, paresthesia, seizures, and diarrhea. Poisoning with muscarine, which is present in certain poisonous mushrooms (Chapter 110), results in increased salivation, sweating, and lacrimation followed by nausea, abdominal pain, and diarrhea.

Medicinal drugs that may induce an autonomic peripheral neuropathy include cisplatin, vincristine, amiodarone, metronidazole, perhexiline maleate, and paclitaxel. Many drugs are capable of increasing or decreasing sweating (Table 427-3).

Nutritional deficiencies that lead to autonomic dysfunction include alcoholic neuropathy, which is a dying-back neuropathy identical to that of beriberi that is caused by thiamine deficiency (Chapter 425). Distal parts of the vagus nerve are affected early, and orthostatic hypotension may occur in more advanced stages. Subacute combined degeneration from vitamin B_{12} deficiency (Chapter 225) results in axonal degeneration and is occasionally manifested as orthostatic hypotension. Autonomic neuropathy has been described in some cases of celiac disease (Chapter 142).

Amyloidosis (Chapter 194) results from the focal deposition of insoluble fibrillary proteins arranged in β-pleated sheet configurations within the extracellular space of various tissues, which may include the vasculature of peripheral autonomic nerves and sympathetic ganglia. Amyloid neuropathy is typically manifested as a painful distal small fiber sensory and severe autonomic neuropathy. Autonomic dysfunction frequently occurs in primary AL, immunoglobulin light chain–associated disease, and hereditary amyloidosis, but only rarely in reactive or AA amyloidosis.

DIAGNOSIS

Clinical evaluation of autonomic dysfunction begins with a careful history. It is important to distinguish chronic and stable conditions from progressive and episodic phenomena and to recognize the circumstances that provoke or modify symptoms. Orthostatic hypotension, for example, is typically worse in the morning and may be aggravated by prolonged standing, physical exertion, heat, carbohydrate ingestion, or menstruation (Table 427-4).

Bedside Evaluation

The skin examination should assess turgor, pallor, flushing, and acral cyanosis, as well as any asymmetry of sweating, which may be more palpable than

TABLE 427-4 GRADING OF ORTHOSTATIC INTOLERANCE

	SYMPTOM FREQUENCY	ACTIVITIES OF DAILY LIVING IN THE UPRIGHT POSTURE	STANDING TIME (ON MOST OCCASIONS)	ORTHOSTATIC BLOOD PRESSURE
Grade I	Infrequent orthostatic symptoms developing only under conditions of increased stress*	Unrestricted	>15 min	May or may not be abnormal
Grade II	Intermittent orthostatic symptoms occurring at least weekly	Some limitation	>5 min	Some changes in cardiovascular indices, e.g., oscillations, or decrease in pulse pressure by >50%
Grade III	Frequent orthostatic symptoms occurring on most occasions	Marked limitation	>1 min	Orthostatic hypotension is present >50% of the time, recorded on different days
Grade IV	Orthostatic symptoms are consistently present	Incapacitated and unable to stand without presyncope or syncope developing	<1 min	Orthostatic hypotension is severe and consistently present

*Conditions that increase orthostatic stress include dehydration, deconditioning from prolonged bedrest, physical exertion, heat stress, and medications that lower blood pressure or impair adrenergic function.
Adapted from Low PA, Singer W. Update on management of neurogenic orthostatic hypotension. *Lancet Neurol.* 2008;7:451-458.

visible. Signs of pupillary asymmetry, ptosis, mucosal dryness, distal sensory or reflex changes, bradykinesia, or rigidity should be noted.

Blood pressure and heart rate should be measured with the patient supine and again after standing for 1 to 3 minutes and correlated with symptoms. Orthostatic hypotension is defined as a reduction in systolic blood pressure of at least 20 mm Hg or a reduction in diastolic blood pressure of at least 10 mm Hg, with or without symptoms, within 1 to 3 minutes of assuming an erect posture. Neurogenic orthostatic hypotension is typically sustained with continued standing. Measurements taken immediately on standing can be misleading because some healthy young persons without orthostatic hypotension will exhibit transient hypotension within 30 seconds of standing but then recover. Except in patients treated with β-blockers, orthostatic hypotension without reflex tachycardia is evidence of generalized adrenergic failure. If reflex tachycardia occurs, dehydration or excessive venous pooling should be considered.

Some patients with orthostatic intolerance experience an abnormal increase in heart rate rather than a drop in blood pressure on standing. Postural tachycardia syndrome is defined as an increase in heart rate by more than 30 beats per minute or to consistently greater than 120 beats per minute when standing.

Laboratory Evaluation

Laboratory testing depends on the type and distribution of autonomic dysfunction. Investigations may include a complete blood count, fasting glucose, electrolytes, morning cortisol, thyroid function testing, vitamin B_{12} level, and when appropriate, autoimmune markers. Creatine kinase should be checked in patients with hyperthermia.

In a patient with an autonomic neuropathy, seropositivity for any of the characterized paraneoplastic autoantibodies should prompt a careful search for an underlying malignancy, even if the results of routine imaging studies are normal. Positron emission tomography is more sensitive than computed tomography in detecting small tumor foci. In patients with suspected pheochromocytoma, the most sensitive screening test is the free metanephrine level (Chapter 235).

Pupillary responses to the instillation of dilute pilocarpine, epinephrine, and cocaine can assist in the localization of oculosympathetic and oculoparasympathetic deficits. Lacrimal secretion may be quantified by the Schirmer and rose bengal tests (Chapter 276). Sialography may be useful to quantify salivary flow. Salivary gland biopsy may be necessary to diagnose Sjögren's syndrome, particularly the seronegative form.

Manometry and scintigraphic studies are useful in the diagnosis of disorders of gastrointestinal motility. Urodynamic studies can elaborate patterns of urinary bladder dysfunction. Suspected amyloid may require biopsy (Chapter 193).

Ambulatory blood pressure testing (Chapter 67), usually over a period of 24 hours, is useful to detect patterns of nocturnal hypertension, postprandial hypotension, and the labile hypertension of baroreflex failure. Adrenergic function can be assessed noninvasively by tilt table testing (Chapter 62). Adrenergic failure can also be defined by deficient recovery and overshoot of arterial pressure following 15 seconds of expiration at 40 mm Hg. The Valsalva ratio, defined as the maximum heart rate generated by the Valsalva maneuver divided by the lowest heart rate within 30 seconds of the peak, is a measure of parasympathetic cardiovagal function. A sensitive index of cardiovagal function is the heart rate response to sinusoidal deep breathing, which quantifies respiratory sinus arrhythmia.

TREATMENT

Rx

Treatment begins with educating patients about the underlying physiology, helping them avoid exacerbations, and managing their symptoms. In cases of mild dysautonomia, medications may not be needed. Elderly patients may be able to compensate for some of the age-associated decline in autonomic function through regular exercise.

Efforts at treating the underlying cause of an autonomic neuropathy should be pursued. Good control of glucose in patients with diabetes mellitus (Chapters 236 and 237) reduces the rate of complications, including neuropathy. Meticulous foot care can prevent cutaneous and joint trauma, ulceration, and infection of desensitized skin.

Orthostatic Intolerance

The goals of treatment are to increase the time that the patient is able to stand without orthostatic symptoms developing while simultaneously avoiding excessive recumbent hypertension. Mild orthostatic hypotension may respond to conservative measures such as increasing oral hydration (2 to 2.5 L/day), drinking sports beverages, and adding dietary salt or sodium tablets to increase daily salt intake to 10 to 20 g. Prolonged bedrest and medications that could potentially exacerbate orthostatic hypotension should be avoided if possible. Elevating the head of the bed by inserting 4- to 6-inch blocks under the head posts can improve orthostatic tolerance by reducing nocturnal natriuresis and stimulating release of renin.

Water bolus treatment (drinking 16 oz of water) can increase systolic blood pressure by 20 mm Hg for about 2 hours by a sympathetic reflex. Lower extremity resistance strength training combined with education about physical countermaneuvers (leg crossing, squatting, bending forward, or placing one foot on a chair) can help patients increase venous return to the heart and improve orthostatic tolerance by activating leg muscles.[1] Compressive stockings are effective if they are tightly fitting, especially if they provide abdominal compression in addition to leg compression.[2] However, they may be poorly tolerated in warm climates and are cumbersome to apply.

Pharmacologic measures include fludrocortisone (0.1 to 0.4 mg/day) to expand plasma volume, midodrine (5 to 10 mg three times daily) to constrict capacitance vessels,[3] and pyridostigmine (30 to 60 mg two or three times daily) to enhance ganglionic transmission during orthostatic stress.[4] Pyridostigmine has a more modest pressor effect but has the advantage of inducing less supine hypertension.[5] Yohombine (5.4 mg three times daily) improves orthostatic hypotension by engaging residual sympathetic tone.[6] Droxidopa (100 to 600 mg three times daily), an orally active synthetic precursor of norepinephrine, is approved in Japan for the treatment of orthostatic hypotension and is under study in the United States. Nocturnal hypertension may be minimized by avoiding pressor agents within several hours of bedtime, elevating the head of the bed, or having a nighttime snack. In severe cases, bedtime hydralazine (25 mg), nifedipine (10 mg), amlodipine (2.5 to 5 mg), or a nitroglycerin patch (0.1 mg/hr) may be needed.

Postprandial hypotension may be managed by dividing meals to avoid large carbohydrate loads. Caffeine or midodrine with breakfast may be helpful.

Sweating Disorders

Initial therapy for palmar hyperhidrosis begins with tap water iontophoresis, in which a low-level electric current applied to the skin surface blocks sweat ducts at the level of the stratum corneum; for severe cases, endoscopic thoracic sympathotomy is effective. Focal hyperhidrosis, such as gustatory sweating caused by aberrant innervation of the facial sweat glands

by regenerating parasympathetic fibers of the facial nerve, responds well to botulinum toxin injections. Generalized hyperhidrosis can be suppressed by oral anticholinergic drugs (e.g., glycopyrrolate, 1 to 2 mg one to three times daily), which tend to be well tolerated because very little crosses the blood-brain barrier; dry mouth is an invariable side effect. Aluminum chloride hexahydrate (20%) in anhydrous ethyl alcohol applied topically to dry skin at bedtime), oral belladonna (0.2 mg 1 to 2 times daily), propantheline (15 mg three times daily), topiramate (beginning at 25 mg twice daily), and clonidine (0.1 mg three times daily orally or by transdermal patch) may also be helpful for hyperhidrosis. Botulinum toxin types A and B, injected intradermally, are effective for axillary hyperhidrosis.

In a patient who is unable to sweat, hyperthermia cannot be prevented by drinking more water. Seeking shade, avoidance of exertion in hot weather, moistening the skin with a wet washcloth, and the use of portable fans can be quite effective. Carbonic acid inhibitors such as topiramate and zonisamide, which can inhibit thermoregulatory sweating, should be avoided if patients experience heat intolerance.

PROGNOSIS

The prognosis depends on the nature of the autonomic disorder. In general, the development of orthostatic hypotension worsens the prognosis.

A diagnosis of multiple system atrophy carries an estimated life expectancy of 7 to 9 years. A patient with pure autonomic failure may have a prolonged and stable clinical course, but it is not unusual for this syndrome to progress years later to a phenotype of multiple system atrophy or dementia with Lewy bodies. Amyloid neuropathy portends a median survival of less than 1 year if orthostatic hypotension is present. Diabetic autonomic neuropathy is associated with an approximately two-fold increased risk for silent myocardial ischemia and overall mortality.

Regional Sympathetic Dysfunction

Regional sympathetic dysfunction may accompany the pain that sometimes follows peripheral nerve injuries. For example, sympathetic activation can occur as a normal physiologic response to any painful state.

Complex regional pain syndrome is characterized by severe, ongoing neuropathic pain that is disproportionate in intensity, duration, and distribution to the expected sequela of limb trauma. In this syndrome, allodynia (pain in response to normally nonpainful stimuli, such as light touch or cold) or hyperalgesia (increased sensitivity to painful stimuli) accompany cutaneous vasomotor or sudomotor abnormalities. The vasomotor changes are manifested as vasodilation with a warm, red or swollen limb or, alternatively, as vasoconstriction with a cold, pale limb. The sudomotor findings range from regional hyperhidrosis to anhidrosis. Regional dystrophic changes, such as dry atrophic skin, sparse or coarse hair, brittle nails, and osteopenia, may also develop. Although sympathetic dysfunction may be pronounced, it does not appear to cause the pain. The mechanisms of pain and sympathetic dysfunction in this condition are incompletely understood and may result from crosstalk among aberrantly regenerated peripheral nerve fibers, expression of new α-adrenergic receptors on sensory nerve fibers and sweat glands, release of substance P and pro-inflammatory peptides at the site of injury, and sensitization of pain-mediating structures at multiple levels within the central nervous system.

Mobilization of the affected limb is of paramount importance in the early treatment of complex regional pain syndrome. A primary goal of analgesic medication or regional anesthesia in early treatment is to facilitate participation in physical therapy. Randomized controlled trials report improvement with the use of bisphosphonates (e.g., alendronate, 40 mg orally or 7.5 mg intravenously daily), steroids (e.g., prednisone, 40 mg daily, or methylprednisolone, 8 mg four times daily initially and then tapered), dimethyl sulfoxide (50% cream one to four times daily), epidural clonidine (300 to 700 µg daily), intrathecal baclofen (25 to 75 µg daily), and epidural spinal cord stimulation. One randomized trial of intravenous immunoglobulin, 0.5 g/kg, found that pain was reduced. ■

PERIPHERAL NEUROPATHIES

MICHAEL E. SHY

APPROACH TO PERIPHERAL NEUROPATHIES

DEFINITION AND PATHOBIOLOGY

Peripheral neuropathy is a general term for disorders affecting peripheral nerves. The peripheral nervous system consists of motor, sensory, and autonomic neurons that extend outside the central nervous system (CNS) and are ensheathed by Schwann cells or ganglionic satellite cells. The peripheral nervous system includes the dorsal and ventral spinal roots, spinal and cranial nerves, sensory and motor terminals, and part of the autonomic nervous system. Motor neurons extend from their cell body in the ventral horn of the spinal cord to the neuromuscular junctions at the muscle that they innervate. The cell bodies of primary sensory neurons lie outside the spinal cord in the dorsal root ganglia, where they extend peripherally to specialized sensory end organs, including nociceptors, thermoreceptors, and mechanoreceptors. Central projections from dorsal root ganglia enter the spinal cord through the dorsal roots. At each spinal segment, the ventral roots, which carry motor axons, and the dorsal roots, which carry sensory axons, join to form mixed sensorimotor nerves. In the cervical, brachial, and lumbosacral areas, the mixed spinal nerves form plexuses from which arise the major anatomically defined limb nerves. Each mixed nerve is composed of large numbers of myelinated and nonmyelinated nerve fibers of varying diameter. The large myelinated axons include motor neurons and large fiber sensory nerves that mediate position and vibration sense. Small, thinly myelinated and nonmyelinated axons primarily provide nociception and autonomic functions. Preganglionic sympathetic autonomic fibers begin in the intermediolateral column of the spinal cord and synapse in ganglia of the sympathetic trunk. Preganglionic parasympathetic fibers travel long distances from their cell bodies in the brain stem or sacral spinal cord to reach terminal ganglia near the organs that the parasympathetic fibers innervate.

CLINICAL MANIFESTATIONS

Symptoms of peripheral neuropathy include weakness, sensory loss, abnormal balance, and autonomic dysfunction. Weakness is often distal and more severe in the legs than the arms. Deep and superficial muscles that are innervated by the peroneal nerve, such as the tibialis anterior and peroneus brevis and longus muscles, often cause more symptoms than do the plantar flexion muscles innervated by the tibial nerve, such as the gastrocnemius. As a result, tripping on a carpet or curb and ankle sprains are frequent symptoms. In the hands, symptoms typically involve fine movements, such as using buttons or zippers and inserting and turning keys in locks. Cramps, the painful knotting of a muscle, frequently occur with motor or sensorimotor neuropathies.

The sensory symptoms of neuropathy reflect disease of small, thinly myelinated or nonmyelinated fibers subserving pain and temperature, as well as large myelinated fibers subserving position sense. Common symptoms of small fiber sensory neuropathy include feeling as though the feet are "walking on pebbles" or "ice cold" and difficulty determining whether bath water is hot or cold with the foot. Painful dysesthesias, such as feeling as though the feet

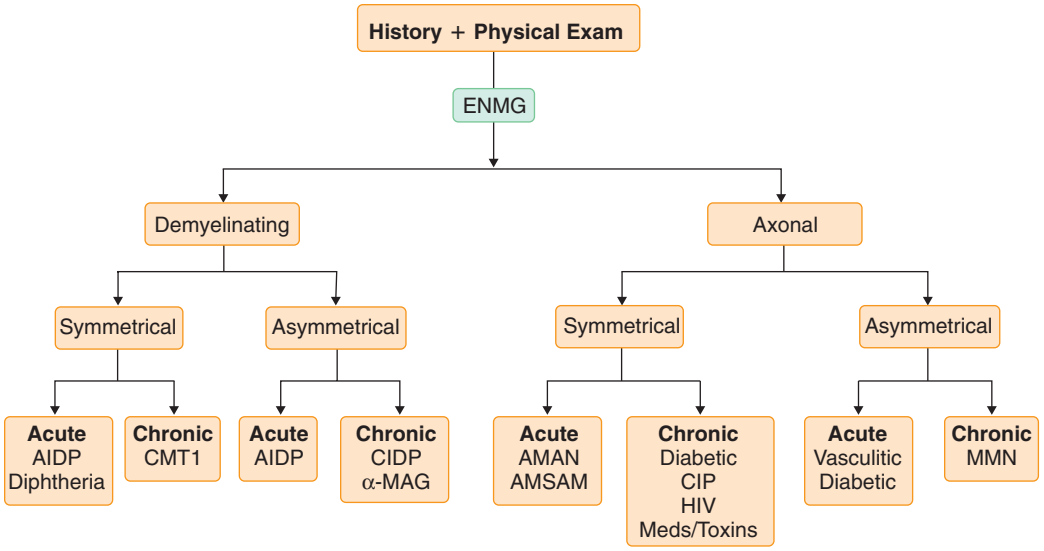

FIGURE 428-1. A systematic approach to evaluate neuropathy. The diseases listed are examples of neuropathies associated with specific neurophysiologic and clinical findings. Diabetic distal, predominantly sensory neuropathies are manifested as chronic axonal neuropathies; acute asymmetrical neuropathies can also occur with diabetes. Most neuropathies caused by toxins or by side effects of medication are chronic, symmetrical axonal neuropathies. AIDP, AMAN, and AMSAN are subtypes of Guillain-Barré syndrome. These and other examples are discussed in more detail in the text. AIDP = acute inflammatory demyelinating polyradiculoneuropathy; AMAN = acute motor axonal neuropathy; AMSAN = acute motor and sensory axonal neuropathy; CIDP = chronic inflammatory polyradiculoneuropathy; CIP = chronic illness polyneuropathy; CMT1 = Charcot-Marie-Tooth disease type 1, a genetic disorder; ENMG = electroneuromyography; HIV = human immunodeficiency virus–related neuropathy; α-MAG = anti-myelin-associated glycoprotein; MMN = multifocal motor neuropathy.

are "on fire," "on hot coals," or "stuck with pins," are also associated with small fiber abnormalities. Similar symptoms occur less frequently in the hands because most neuropathies are dependent on the length of the nerves; as a general rule, sensory symptoms begin in the hands when sensory symptoms in the legs have progressed up to the knee. An exception is when the patient also has carpal tunnel syndrome, which is often manifested as pain and tingling in the hands and can awaken patients from sleep. Large fiber sensory loss usually impairs balance, which may be worse at night when vision cannot overcome the loss of proprioception. Loss of proprioception is also frequently length dependent, so a patient may improve balance by lightly touching a wall with the hand to improve proprioceptive input to the brain.

Autonomic symptoms are frequent in neuropathies associated with diabetes or amyloidosis and include urinary retention or incontinence, abnormalities of sweating, constipation alternating with diarrhea, and lightheadedness when standing. Impotence is frequent.

DIAGNOSIS

Systematic Approach to Patients with Peripheral Neuropathy

Evaluation begins with the history and physical examination to demonstrate peripheral nerve disease and proceeds to neurophysiologic testing to characterize whether the process is demyelinating or axonal. Other specific tests are then ordered (Fig. 428-1).

Peripheral neuropathies usually affect both motor and sensory nerves, thereby causing both weakness and sensory loss. However, certain neuropathies are predominantly sensory, such as diabetes, or motor, such as multifocal motor neuropathy (Tables 428-1 and 428-2). Most neuropathies are symmetrical and length dependent. Pronounced asymmetries in symptoms suggest specific disorders, such as mononeuritis multiplex or hereditary neuropathy with liability to pressure palsies. It is also useful to know whether symptoms are acute (<1 month), subacute (<6 months), or chronic (>6 months). For example, Guillain-Barré syndrome develops over a period of days to weeks, whereas chronic inflammatory demyelinating polyneuropathy (CIDP) evolves over months, and inherited neuropathies may develop over years.

Neurologic Examination

Wasting of muscle is prominent in many sensorimotor or motor neuropathies, regardless of whether they are primary axonal or primary demyelinating disorders, because even demyelinating neuropathies are associated with secondary axonal degeneration. Atrophy frequently occurs in muscles of dorsiflexion, such as the tibialis anterior, and in intrinsic hand muscles, such as the first dorsal interosseus. Fasciculations, which appear as small twitches of the muscle, are sometimes present, particularly in axonal neuropathies.

Weakness is often most pronounced in foot dorsiflexion and eversion and in the intrinsic hand muscles. In the lower extremities, weakness usually progresses to the muscles of plantar flexion before more proximal muscles become involved.

TABLE 428-1 PREDOMINANTLY SENSORY NEUROPATHIES

CLASSIFICATION	SUBGROUP	TYPE	FIBERS
Genetic		HSAN	Large, small
Inflammatory, immune	Monoclonal gammopathy	Anti-MAG (early on)	Mainly large
	Vasculitis	Sjögren's syndrome	Large, small
	Paraneoplastic	Anti-Hu	Large
Metabolic	Diabetic	Distal symmetrical polyneuropathy	Large, small
Infectious	HIV	HIV neuropathy	Small
	Herpes zoster	Focal radiculoneuropathy	Small
	Leprosy	Tuberculoid	Small
Toxic, deficiency	Medications	Vincristine	Small
		Paclitaxel	Large
		Cisplatin	Large
		Thalidomide	Large
		NRTIs	Small
	Toxins	Thallium	Small
		Acrylamide	Large
		Pyridoxine (B_6)	Large, small
	Deficiency states	Vitamin B_1	Large, small
		Vitamin B_{12}	Large
		Vitamin E	Large
Idiopathic	Frequent		Large, small

HIV = human immunodeficiency virus; HSAN = hereditary sensory and autonomic neuropathy; MAG = myelin-associated glycoprotein; NRTIs = nucleoside reverse transcriptase inhibitors.

TABLE 428-2 PREDOMINANTLY MOTOR NEUROPATHIES

CLASSIFICATION	SUBGROUP	TYPE
Genetic		HMN
Inflammatory, immune	Guillain-Barré	AMAN
	Multifocal motor neuropathy	MMN
	Critical illness myopathy	CIM
Toxic, deficiency	Medications	Dapsone
	Toxins	Lead (adults)

AMAN = acute motor axonal neuropathy; CIM = critical illness myopathy; HMN = hereditary motor neuropathy; MMN = multifocal motor neuropathy.

Sensory loss is usually in a stocking-glove distribution in both large and small fiber neuropathy. Cold, erythematous, or bluish discolored feet suggest loss of small fiber function. Large fiber sensory loss, or *sensory ataxia*, in the upper extremities can often be detected by an inability of the patient to locate the thumb accurately with the opposite index finger while the eyes are closed or by the presence of a characteristic irregular tremor (pseudoathetosis) of the fingers.

The sensory examination should include vibration, position, and light touch as well as pain and temperature. It is important to determine the degree and extent of sensory loss in addition to the pattern of deficits (symmetrical or asymmetrical; distal or generalized; focal, multifocal, or diffuse).

The complete absence of reflexes early in the course of a neuropathy suggests a demyelinating neuropathy ; for example, the absence of reflexes in early childhood is often the first detectable abnormality in children with inherited demyelinating neuropathies. Alternatively, the absence of ankle reflexes but the presence of normal patellar or upper extremity reflexes is common in "dying back" (length-dependent) axonal neuropathies, both acquired and inherited. Reflexes may be present in small fiber neuropathies.

On gait testing, subtle weakness in the feet can be detected by an inability of the patient to heel walk. Sensory ataxia can be appreciated by a wide-based gait or inability to tandem walk.

Neurologic Testing

Neurophysiology

Electromyography (EMG) and nerve conduction studies can determine whether a neuropathy is primarily demyelinating or axonal and can confirm whether the process is symmetrical or asymmetrical (Chapter 403).

Motor nerve conduction velocities measure conduction over the main body of nerves but not their proximal or distal portion. Distal motor latencies and F wave latencies measure velocities over the distal and proximal portions of the nerves. When slowing is roughly the same over the proximal, distal, and main portion of the nerve, the slowing is said to be uniform. When the slowing is multifocal or asymmetrical, either along the same nerve or between different nerves, the slowing is said to be nonuniform. Slowed conduction velocities (to less than 70% of normal) suggest that the neuropathy is primarily demyelinating.

The sensory nerve action potential is a summation of action potentials from individual large-diameter sensory axons. In axonal neuropathies, amplitudes of the compound muscle action potential or sensory nerve action potential are reduced. When there has been a loss of individual sensory axons, amplitudes of the sensory nerve action potential are reduced.

The presence of spontaneous activity on EMG, such as fibrillations or positive sharp waves, suggests that an acute or active process is damaging axons and denervating muscle. The presence of large, polyphasic motor units suggests partial reinnervation of muscle by regenerating axons (i.e., a more chronic process). Recruitment of motor units is also reduced in patients with demyelinating and axonal neuropathies.

Quantitative Sensory Testing

Quantitative sensory testing can assess and quantify vibratory, thermal, or painful sensory function in patients with peripheral neuropathies or other sensory disorders. Although the stimulus is an objective physical event, the response represents a subjective report and requires cooperation from the patient; as a result, this test by itself cannot diagnose sensory neuropathies or sensory loss.

Nerve and Skin Biopsy

Nerve biopsy is occasionally indicated to address specific questions, such as whether vasculitis, tumor, or another infiltrative or metabolic disorder is present. Biopsy of sural nerves is performed just above the ankle. After biopsy, patients lose sensation over the region on the lateral aspect of the foot that is innervated by the sural nerve, and transient painful dysesthesias may develop around the biopsy site. Teased sural nerve fiber analysis can demonstrate segmental demyelination or remyelination, and electron microscopy can demonstrate features of nerve regeneration and identify specific pathologic processes.

Epidermal skin biopsies with quantification of the loss of small epidermal nerve fibers may aid in the diagnosis of sensory neuropathies, particularly in neuropathies that involve a loss of small fibers, such as diabetes mellitus, human immunodeficiency virus (HIV) infection, or chemotherapeutic drugs. Skin biopsies also are increasingly being used to evaluate myelinated sensory nerves.

Laboratory Findings

Evaluation of all patients with suspected neuropathy should include blood glucose and creatinine levels as well as a complete blood count (including red blood cell indices to detect possible macrocytosis). If the history and EMG are consistent with exposure to a toxin or a vitamin-deficiency state, specific testing is indicated. Most patients should also have vitamin B_{12} level measurement (Chapter 167), rapid plasmin reagent test (Chapter 327), and serum immunofixation electrophoresis for possible monoclonal gammopathy (Chapter 193). In unexplained sensory neuropathies, HIV testing should be considered (Chapter 401). In selected patients, electrodiagnostic studies will suggest the need to test for specific antibodies, such as antibodies reacting to ganglioside GM_1 or myelin-associated glycoprotein (MAG). Genetic testing is most cost-effective when selection of candidate genes is based on the patient's nerve conduction studies, inheritance pattern, and clinical findings.

INHERITED NEUROPATHIES

DEFINITION

Inherited neuropathies are frequently called Charcot-Marie-Tooth (CMT) disease based on the names of the three physicians who initially characterized the disorders in the late 19th century. They are also referred to as hereditary motor and sensory neuropathies, hereditary motor neuropathies, or hereditary sensory and autonomic neuropathies, depending on their clinical manifestation. Autosomal dominant forms are subdivided into demyelinating (CMT1) and dominantly inherited axonal (CMT2) forms based on electrophysiologic and neuropathologic criteria. X-linked (CMTX) and autosomal recessive (CMT4) forms are also seen. Each type of CMT disease is subdivided according to the specific genetic cause of the neuropathy. For example, the most common form of CMT1, termed CMT1A, is caused by a duplication of a fragment of chromosome 17 containing the peripheral myelin protein 22-kD (*PMP22*) gene (see later). Currently, mutations in more than 40 genes have been identified as causes of inherited neuropathies (available at *www.uia.ac.be/CMTMutations/*) (Table 428-3).

EPIDEMIOLOGY

The prevalence of CMT is about 1 in 2500 people, without ethnic predisposition. The 17p11.2 duplication causing CMT1A accounts for 60 to 70% of CMT1 patients, CMT1X for approximately 10 to 20% of CMT cases, CMT1B for less than 5% of patients, and CMT2 for about 20% of cases. The prevalence of hereditary neuropathy with liability to pressure palsies is not known, but about 85% of patients with clinical evidence of this syndrome have a chromosome 17p11.2 deletion.

PATHOBIOLOGY

Pathology

Segmental demyelination, remyelination, and axonal loss are characteristic features of the various demyelinating forms of CMT1. In Dejerine-Sottas neuropathy, the demyelination is more severe. In CMT1, onion bulbs of concentric Schwann cell lamellae are usually present on nerve biopsies, with loss of both small- and-large diameter myelinated fibers and sometimes axons. Focal, sausage-like thickenings of the myelin sheath (tomacula) are characteristic of hereditary neuropathy with liability to pressure palsies (HNPP) but may also be found in other forms of CMT1, particularly CMT1B. In CMT1, disability typically correlates better with secondary axonal degeneration than with demyelination itself, thereby demonstrating the importance of Schwann cell–axonal interactions in demyelinating disease (Fig. 428-2).

Genetics

Mutations in *PMP22* and *MPZ* cause CMT1, and mutations in *GJB1* cause CMT1X. All three genes code for myelin proteins. Mutations in the neurofilament light (*NEFL*), gigaxonin (*GAN*), and *dynactin* genes cause CMT2; all three genes have roles in the axonal cytoskeleton and axonal transport. LITAF/SIMPLE, the myotubulin-related proteins 2 and 13, and RAB7 are involved in intracellular trafficking. MFN2 and ganglioside-induced differentiation-associated protein-1 (GDAP1) are nuclearly encoded mitochondrial proteins.

CLINICAL MANIFESTATIONS

Despite phenotypic variability, the typical clinical course of CMT1 and CMT2 patients includes normal development before weakness, and sensory loss appearing gradually within the first two decades of life. Affected children are often slow runners and have difficulty with activities that require balance (e.g., skating, walking across a log). Ankle-foot orthoses are frequently required by the third decade. Fine movements of the hands for activities such

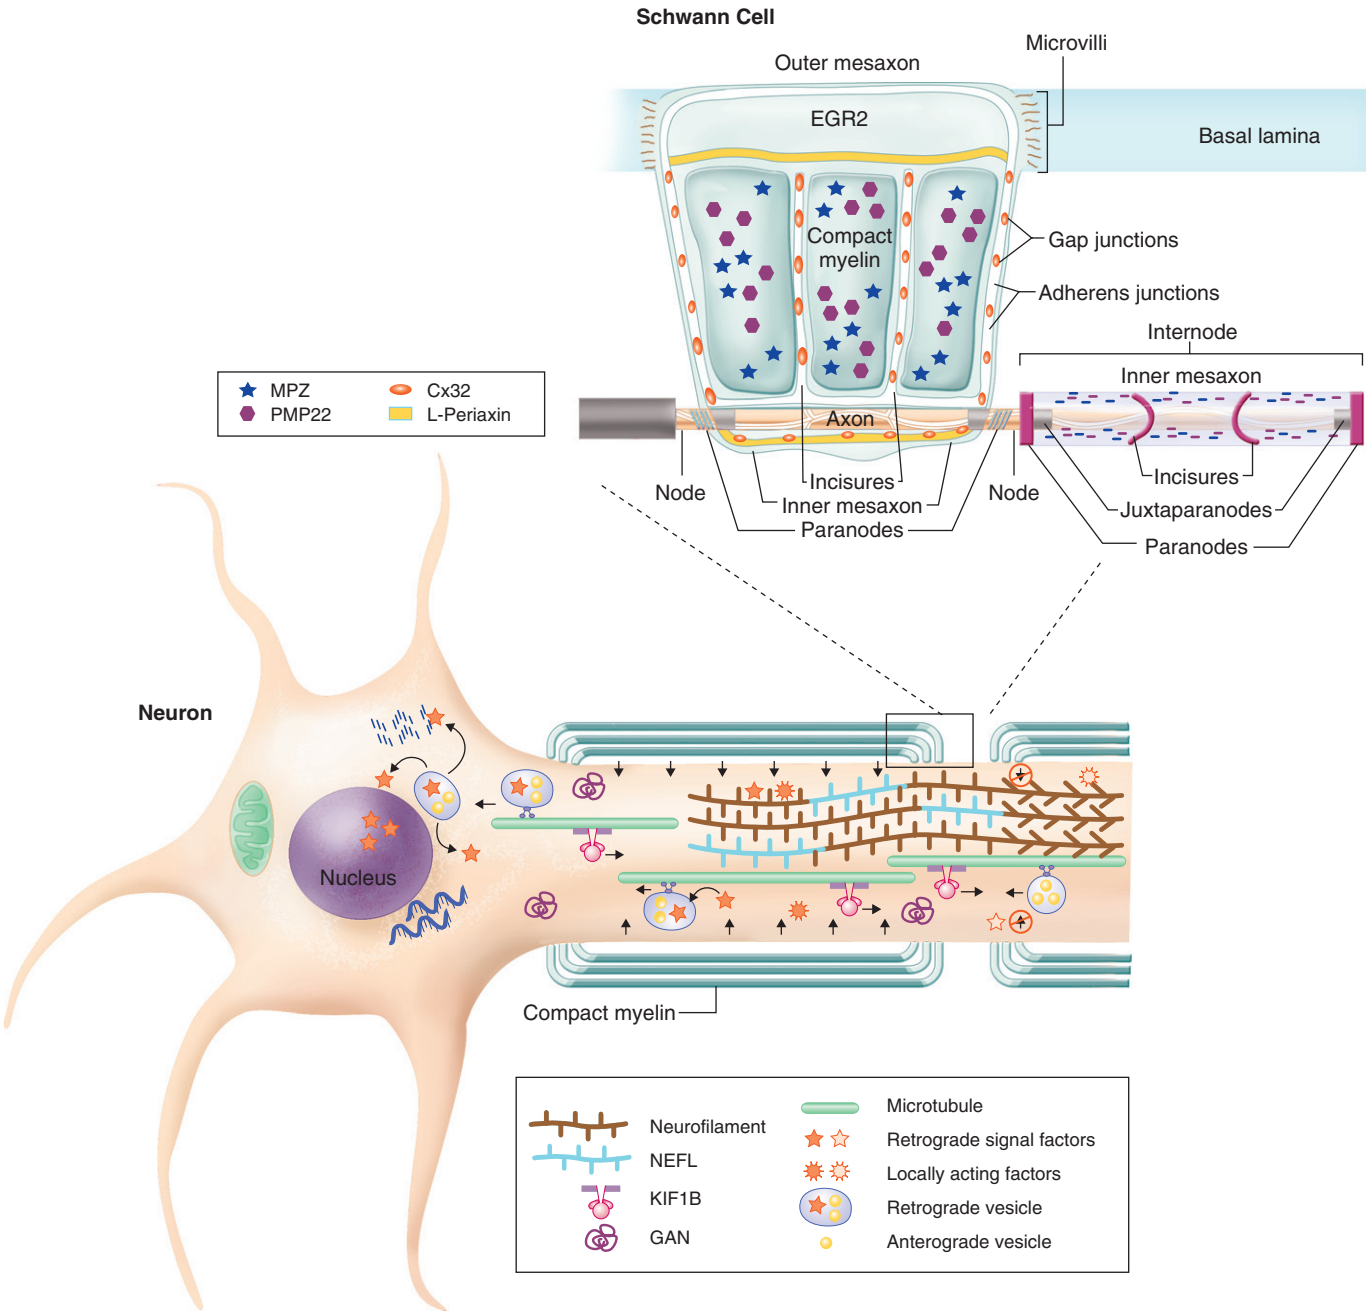

FIGURE 428-2. Schematic view of an axon and its myelinating Schwann cell. Proteins mutated in inherited peripheral neuropathies are shown in color at their cellular location. In the *upper part* of the panel, the myelinating Schwann cell has been unraveled to show the nucleus and regions of both compact myelin and noncompact myelin. Cytoskeletal elements within the axon are also illustrated. (From Shy ME, Garbern JY, Kamholz J. Hereditary motor and sensory neuropathies: a biological perspective. *Lancet Neurol.* 2002;1:110-118.)

as turning a key or using buttons and zippers may be impaired, but the hands are rarely as affected as the feet. Most patients remain ambulatory throughout life and have a normal lifespan.

A minority of CMT patients have a more severe phenotype with delayed motor milestones and onset in infancy, termed *Dejerine-Sottas neuropathy.* Especially severe cases are classified as congenital hypomyelination if myelination appears to be disrupted during embryologic development. Many patients have de novo autosomal dominant disorders, and the term *Dejerine-Sottas neuropathy* is currently used primarily to denote severe early-onset clinical phenotypes regardless of the inheritance pattern. Patients with hereditary motor neuropathies sometimes have mild sensory abnormalities, and patients with hereditary sensory and autonomic neuropathies usually have some weakness. The same mutations in the same gene (*GARS*) cause both CMT2D and hereditary motor neuropathy type V.

DIAGNOSIS

Molecular testing, performed after the family history, neurologic examination, and neurophysiologic testing have suggested the probable candidate genes (GeneClinics—available at *www.geneclinics.org*), is the "gold standard" for the diagnosis of inherited neuropathies. Nerve conduction velocity testing can distinguish between demyelinating and axonal neuropathies. Most CMT1 patients, particularly those with CMT1A, have a uniformly slow nerve conduction velocity of about 20 m/second. Asymmetrical slowing, which is characteristic of hereditary neuropathy with liability to pressure palsies, may be found in patients with missense mutations in *PMP22*, *MPZ*, *EGR2*, and *GJB1*. Although CMT2 is characterized by axonal loss and reduced compound muscle action potential or sensory nerve action potential amplitudes, virtually all forms of CMT1 have axonal loss as well as demyelination.

Differential Diagnosis

Inherited neuropathies must be distinguished from acquired neuropathies (see later). Additionally, genetic disorders of the CNS such as hereditary spastic paraplegia (Chapter 417) or leukodystrophies (Chapter 419) may mimic inherited neuropathies by causing length-dependent weakness, sensory loss, and foot deformities such as pes cavus; these patients will frequently have upper motor neuron signs, such as increased reflexes or Babinski's signs, and do not have neurophysiologic evidence of neuropathy.

TREATMENT

Rx

There is no specific therapy for the inherited neuropathies, but clinical and genetic counseling and symptomatic and rehabilitative treatment are important. A detailed family history and often examination of family members are required for prognosis and genetic counseling.

Ankle-foot orthoses to correct footdrop may return gait and balance to normal for years. Foot surgery is sometimes offered to correct inverted feet, pes cavus, and hammertoes. Surgery may improve walking, alleviate pain over pressure points, and prevent plantar ulcers. However, foot surgery is generally unnecessary and does not improve weakness and sensory loss.

Ascorbic acid, antagonists to progesterone, and subcutaneous injections of neurotrophin 3 have demonstrated improvement in animal models of CMT1A. However, no medication has yet demonstrated efficacy in patients with CMT1A or any other form of CMT.

INFLAMMATORY AND IMMUNOLOGIC NEUROPATHIES

Guillain-Barré Syndrome

DEFINITION

Guillain-Barré syndrome refers to acquired, inflammatory peripheral neuropathies that have (1) an acute onset, (2) elevated cerebrospinal fluid (CSF) protein levels with low CSF cell counts (cytoalbuminologic dissociation), and (3) a monophasic illness with at least partial recovery. Guillain-Barré syndrome is subdivided into acute inflammatory demyelinating polyneuropathy, acute motor and sensory axonal neuropathy, acute motor axonal neuropathy, and Miller-Fisher syndrome (Table 428-4).

EPIDEMIOLOGY

Acute inflammatory demyelinating polyneuropathy accounts for up to 97% of cases of Guillain-Barré syndrome in North America and Europe. It is a sporadic disorder with an incidence of 0.6 to 1.9 cases per 100,000 people in North America and Europe. Men are more likely to be affected than women (1.4:1). In 60% of cases, acute inflammatory demyelinating polyneuropathy is preceded by a respiratory tract infection (e.g., cytomegalovirus [Chapter 384], Epstein-Barr virus [Chapter 385], or gastroenteritis (*Campylobacter jejuni* [Chapter 311]). Acute motor axonal neuropathy and acute motor and sensory axonal neuropathy are rare in North America and Europe but more frequent in China, Japan, Mexico, Korea, and India.

PATHOBIOLOGY

All forms of Guillain-Barré syndrome probably result from postinfectious molecular mimicry in which nerve antigens are attacked by the immune system because they resemble antigens presented by microbes, in particular, *C. jejuni*. For example, the HS/0:19 serotype of *C. jejuni* is common in northern Chinese patients with Guillain-Barré syndrome and has also been isolated from such patients in other countries. Assays with antiganglioside antibodies, bacterial toxins, and lectins have characterized potential immunogenic regions of diarrhea-associated *C. jejuni* strains. However, it is not clear that molecular mimicry is the cause of acute inflammatory demyelinating polyneuropathy, which is the most common form in the United States and Europe.

CLINICAL MANIFESTATIONS

Weakness, which is the most common initial symptom in both acute inflammatory demyelinating polyneuropathy and acute motor and sensory axonal neuropathy, can be mild, such as difficulty walking, or severe, such as total quadriplegia and respiratory failure. Bilateral weakness of facial muscles (facial diplegia) occurs in about 50% of cases. The most common manifestation is leg weakness that subsequently "ascends" into the arms. Although Guillain-Barré syndrome has been described as an "ascending paralysis," proximal weakness is common, and 5% of cases have isolated cranial nerve involvement that subsequently descends into the limbs. Sensory loss occurs in most patients. The autonomic nervous system is involved in about 65% of patients.

Length-dependent weakness without sensory loss develops in patients with acute motor axonal neuropathy, including cranial nerve involvement in about 25%. Miller-Fisher syndrome consists of the triad of ophthalmoplegia, ataxia, and areflexia. Facial weakness, ptosis, and pupillary abnormalities may be present. Nerve conduction velocities in Miller-Fisher syndrome are generally normal, unlike the case with acute inflammatory demyelinating polyneuropathy.

DIAGNOSIS

The diagnosis of acute inflammatory demyelinating polyneuropathy and acute motor and sensory axonal neuropathy is based on the history, physical examination, and CSF evaluation. Deep tendon reflexes are decreased or absent, and the CSF is abnormal with cytoalbuminologic dissociation. The weakness is symmetrical. The presence of CNS abnormalities should cast doubt on the diagnosis. Acute inflammatory demyelinating polyneuropathy is distinguished from acute motor and sensory axonal neuropathy by nerve conduction studies. In both acute inflammatory demyelinating polyneuropathy and acute motor and sensory axonal neuropathy, the CSF should have fewer than five white blood cells (WBCs)/mL. If the CSF cell count is greater than 50 WBCs/mL, another diagnosis, such as HIV infection (Chapter 401) or Lyme disease (Chapter 329), should be considered. Elevated CSF protein may not be apparent in the first 7 to 10 days of the illness; in up to 10% of cases, CSF protein levels remain normal. Approximately 5% of patients with Guillain-Barré syndrome have Miller-Fisher syndrome, and more than 85% of these patients have polyclonal antibodies that react with the ganglioside GQ_{1b}.

Differential Diagnosis

The differential diagnosis varies in different parts of the world. Historically, poliomyelitis (Chapter 423) was the major cause of acute flaccid quadriparesis. In North America, polio has been eradicated, but other viral illnesses may induce polio-like syndromes: ECHO 70 (Chapter 387), coxsackievirus

TABLE 428-4 INFLAMMATORY AND IMMUNE-RELATED NEUROPATHIES

DISORDER	TYPE	CLINICAL TRAITS	PATHOBIOLOGY	TREATMENT*
Guillain-Barré syndrome	AIDP	Acute flaccid weakness, sensory loss	Demyelination, lymphocyte infiltration	Plasma exchange, IVIG
	AMAN/AMSAN	Acute flaccid weakness, no sensory loss in AMAN	Molecular mimicry, association with *Campylobacter jejuni*	? Plasma exchange or IVIG
	Fisher's syndrome	Acute ataxia, ophthalmoparesis and areflexia	Anti-GQ1b antibodies	? Plasma exchange or IVIG
CIDP		Slower onset of weakness, sensory loss	Inflammatory/immune-mediated demyelination	Corticosteroids, plasma exchange, IVIG
Monoclonal gammopathy	IgM	Sensory > motor	Particularly anti-MAG	Immune suppression (Chapter 193)
	IgG	Sensorimotor	Many probably chance associations, osteosclerotic myeloma, solitary plasmacytoma; POEMS may be immune mediated	Treatment of myeloma
Multifocal motor neuropathy		Pure motor	Focal demyelination, antibodies to GM_1 frequent	IVIG

*Typical regimens: IVIG, 0.4 g/kg/day × 5 days for a total of 2 g/kg; may be repeated monthly as needed. Corticosteroids: prednisone, 60 to 80 mg/day for up to 3 months, followed by gradual tapering, depending on the clinical response, with a goal to about 20 mg on an alternate-day regimen.

AIDP = acute idiopathic demyelinating polyneuropathy; AMAN = acute motor axonal neuropathy; AMSAN = acute motor and sensory axonal neuropathy; CIDP = chronic inflammatory polyradiculoneuropathy; IgG = immunoglobulin G; IVIG = intravenous immune globulin; MAG = myelin-associated glycoprotein; POEMS = polyneuropathy, organomegaly, M protein, skin changes.

(Chapter 387), West Nile virus (Chapter 390), and rarely, rabies (Chapter 422). Because these diseases are not demyelinating disorders, they can be distinguished from acute inflammatory demyelinating polyneuropathy by their normal nerve conduction velocity. However, the results of electrodiagnostic studies are similar in both acute motor axonal neuropathy and the polio-like syndromes, thus making distinction between acute motor axonal neuropathy and these syndromes difficult.

Tick paralysis (Chapter 390), caused by a toxin within the tick, can mimic Guillain-Barré syndrome, particularly in children. Usually, removal of the tick is associated with improvement within hours, although progression can occur. Progression is particularly likely in Australia, where the toxin differs from that found in North America.

Botulism (Chapters 304 and 430) rapidly produces a flaccid paralysis. Patients have ophthalmoplegia, bulbar weakness, dry mouth, constipation, and orthostatic hypotension, but sensory symptoms do not develop. Other entities that can mimic Guillain-Barré syndrome are acute spinal cord compression (Chapter 407), acute transverse myelitis (Chapter 419), and vascular myelopathies, all of which are characterized by decreased reflexes before the development of upper motor neuron signs such as increased reflexes. Carcinomatous or lymphomatous meningitis can also cause a rapidly developing quadriparesis, but both are associated with elevated CSF WBC counts.

TREATMENT Rx

Patients with Guillain-Barré syndrome require hospitalization because of the potential for respiratory compromise. Pulmonary function tests should be performed frequently; a vital capacity of less than 1 L or a negative inspiratory force of less than −70 suggests that ventilator support may be needed in an intensive care unit setting. Autonomic instability and difficulty swallowing also need to be monitored.

Therapies directed at modulating the immune system are effective in Guillain-Barré syndrome. Intravenous immunoglobulin (IVIG) therapy, which is the preferred treatment, is typically given as 2 g/kg divided over 2 to 5 days within the first 2 weeks. Although plasma exchange and IVIG are equally effective,[1] at least in the first 2 weeks, IVIG is often preferred for its convenience unless there are contraindications, such as low serum immunoglobulin A (IgA) levels, renal failure, or severe hypertension.

Plasma exchange, usually four exchanges of 1.5 L of plasma spread over a 10-day period, is also effective.[2] Two plasma exchanges may be sufficient in mild cases, and six exchanges are not superior to four in severely affected patients. This therapy should ideally be administered within the first 2 weeks and not later than 4 weeks from clinical onset.

Ten percent of patients with Guillain-Barré syndrome relapse after initially responding to plasma exchange or IVIG; they usually respond to a second cycle of the previously effective treatment. The combined use of plasma exchange followed by IVIG does not improve the prognosis.[3]

Corticosteroids in different forms (intravenous methylprednisolone, oral prednisolone or prednisone, intramuscular adrenocorticotropic hormone) are not of benefit. Intravenous methylprednisolone (500 mg/day for 5 days) in association with IVIG has a slight initial advantage over IVIG alone but no benefit in terms of long-term disability.

PROGNOSIS

Fifty percent of patients progress to their nadir, or maximal disability, within 2 weeks, 75% within 3 weeks, and more than 90% within 4 weeks of the onset of symptoms. With modern supportive care, acute mortality is about 2%. After a brief period of stabilization, slow spontaneous recovery occurs over a period of weeks or months. Most patients either undergo complete recovery or are left with minor sequelae; about 20% have a persistent disability. The long-term prognosis depends at least in part on the extent of axonal loss. Patients with low compound muscle action potential amplitudes in the upper extremities are more likely to have a poor prognosis.

Patients with acute motor axonal neuropathy will recover after approximately 2 months, but the extent of recovery may be less than in Guillain-Barré syndrome. In general, the prognosis for recovering from Miller-Fisher syndrome is excellent.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

DEFINITION

CIDP is a chronic acquired demyelinating sensorimotor neuropathy that may be monophasic, relapsing, or progressive. By definition, CIDP develops over at least a 2-month period as opposed to acute inflammatory demyelinating polyneuropathy, which it otherwise resembles.

EPIDEMIOLOGY

CIDP occurs in all age groups, with a mean age range of 30 to 50 years. Women are slightly more likely to be affected than men. Antecedent events are less common than in Guillain-Barré syndrome; they occur in about 30% of patients and include upper respiratory infections, gastrointestinal infections, vaccinations, surgery, and trauma.

PATHOBIOLOGY

CIDP is considered an autoimmune disorder based on pathologic findings in nerve biopsy samples from patients and on findings in animal models such as experimental allergic neuritis, in which a similar disorder follows immunization with peripheral nervous system myelin components and Freund's adjuvant. Nerve biopsy shows macrophage-mediated segmental demyelination, occasional endoneurial lymphocytic T-cell infiltrates, and endoneurial edema. The major histocompatibility complex class I and II antigens are upregulated, and there are often deposits of immunoglobulins and complement split products on the outer Schwann cell membranes or myelin sheaths. CIDP can be passively transferred to animals by patient sera, but no clear autoantigen has been identified.

CLINICAL MANIFESTATIONS

Weakness and sensory loss begin insidiously and progress over a period of months to years. Weakness is commonly proximal as well as distal. Patients can become bedridden. Loss of proprioception from damage to large-diameter sensory nerves may affect balance and result in an action tremor. Deep tendon reflexes are usually absent or markedly decreased. Facial weakness (15%), ptosis or ophthalmoparesis (5%), and papilledema occur occasionally. Variant forms include pure motor, pure sensory, and multifocal disease.

DIAGNOSIS

Diagnosis is based on clinical symptoms and signs, electrodiagnostic studies, and CSF examination. Nonuniform, asymmetrical slowing on nerve conduction studies is characteristic. One portion of a nerve may have different conduction than another. For example, if damage is primarily in the spinal roots, proximal conduction velocities and F wave latencies may be most affected. Compound muscle action potentials are generally reduced because of the concomitant axonal degeneration that occurs with demyelinating neuropathies. However, temporal dispersion and conduction block may also reduce the amplitude of muscle action potential in any demyelinating neuropathy. Sensory nerve conduction is also slow in CIDP, but because sensory nerve action potentials are often not detectable, sensory conduction velocity may be unmeasurable.

CSF results resemble those of acute inflammatory demyelinating polyneuropathy: WBC counts are usually less than 10 cells/mm^3, and protein levels are higher than 60 mg/dL. CSF cell counts higher than 50/mm^3 suggest another diagnosis, such as HIV infection or hematologic malignancy. CSF protein levels may be normal early in the course of CIDP.

Differential Diagnosis

CIDP is distinguished from acute inflammatory demyelinating polyneuropathy by its time course. A similar manifestation can also occur in diabetes, lymphoma, monoclonal gammopathies (see later), and asymmetrical inherited neuropathies (see earlier).

TREATMENT Rx

Corticosteroids are effective in more than two thirds of patients with CIDP. A standard approach is to use oral prednisone (1 mg/kg/day) for 6 to 8 weeks, followed by slow tapering over a 3- to 12-month period to a maintenance level of about 0.1 mg/kg/day. A response to prednisone may take months to occur, and occasional patients may worsen before they respond. As a result, plasma exchange[2] or IVIG[4,5] is often used as initial treatment. Because of the side effects of long-term corticosteroids or the lack of response to them, azathioprine, cyclosporine, cyclophosphamide, methotrexate, mycophenolate mofetil, rituximab, and interferon-α or -β have been used with variable success in uncontrolled reports.

Neuropathy Associated with Monoclonal Gammopathy

DEFINITION

Monoclonal gammopathy refers to the presence in the β-γ region of serum protein electrophoresis of an abnormal spike (variably called a paraprotein, monoclonal protein, or M protein) consisting of immunoglobulins of the same isotype, all produced by a single clone of abnormally proliferating lymphocyte and plasma cells. In some cases, the M protein is part of a malignant lymphoproliferative disease such as multiple myeloma, solitary plasmacytoma (IgG and IgA), Waldenström's macroglobulinemia (IgM) (Chapter 193), lymphoma (Chapter 191), chronic lymphocytic leukemia (IgM) (Chapter 190), primary amyloidosis (Chapter 194), or cryoglobulinemia (Chapter 193). In most instances, however, monoclonal gammopathy is not initially associated with any of these disorders and is classified as a monoclonal gammopathy of uncertain significance (MGUS), although in patients with MGUS, the gammopathy may evolve into a malignant form (Chapter 193).

EPIDEMIOLOGY

Monoclonal gammopathy occurs in up to 8% of patients with peripheral neuropathy of unknown etiology. However, MGUS is frequent, being found in 1% of the population older than 50 years and in 3% older than 70 years, and most subjects with MGUS do not have neuropathy. In some cases, the co-occurrence of neuropathy and M protein may be a coincidence, but in other cases, the M protein is clearly related to the neuropathy.

The prevalence of neuropathy is higher in patients with IgM versus IgG or IgA M proteins. The prevalence of symptomatic neuropathy associated with IgM monoclonal gammopathy in patients older than 50 years is approximately 20 per 100,000. In half of such patients, the M protein reacts either with the HNK1 carbohydrate moiety of MAG or with other glycoproteins (MPZ, PMP22) and glycolipids (sulfoglucuronyl paragloboside [SGPG] and lactosaminyl paragloboside [SGLPG]). IgM M proteins associated with neuropathy may also bind to other neural antigens.

In patients with IgG monoclonal gammopathy and neuropathy, the relationship is less clear than with IgM. Although about 10% of patients with multiple myeloma have neuropathy, in most cases, the M protein does not react with a neural antigen, and patients do not improve with immunotherapy (see later). Conversely, approximately 50% of patients with the osteosclerotic form of myeloma have neuropathy, often associated with the non-neurologic manifestations of *o*rganomegaly, *e*ndocrine abnormalities, and brown, tannish discoloration of the *s*kin. Collectively, the *M* protein, *p*olyneuropathy, and other features are referred to by the acronym POEMS (Chapter 193). Similarly, about 50% of patients with light-chain amyloidosis have neuropathy.

PATHOBIOLOGY

In patients with IgM M proteins that immunoreact with MAG, nerve biopsies demonstrate segmental demyelination with deposits of M protein and complement. The myelin lamellae are often widened on sural nerve biopsies, but a biopsy is not necessary for diagnosis. High titers (>1:10,000) of anti-MAG IgM antibodies are associated with neuropathy, and intraneural or systemic injection of anti-MAG IgM M proteins causes complement-mediated demyelination of nerves in animals.

CLINICAL MANIFESTATIONS

Most patients with anti-MAG neuropathies are initially seen in their sixth to seventh decade of life with dysesthesias and paresthesias in their legs and unsteadiness while walking because of loss of proprioception. Physical examination shows a length-dependent large fiber sensory neuropathy. Weakness may develop later.

DIAGNOSIS

Nerve conduction velocities are slow (about 25 m/second) with pronounced delays in distal motor latencies, thus prompting the designation *distal acquired demyelinating symmetrical neuropathy* to distinguish the disorder from CIDP.

TREATMENT Rx

Treatment of neuropathies associated with monoclonal gammopathy is similar to that for CIDP (see earlier). However, patients with anti-MAG-related neuropathies do not respond as well to treatment as do patients with CIDP. Anecdotal data support the benefit of rituximab in some patients.

PROGNOSIS

Progression of the neuropathy of monoclonal gammopathy disables about 25% of patients after 10 years and 50% after 15 years. The course of patients with osteosclerotic myeloma and neuropathy depends on the response to treatment of the myeloma. In patients whose myeloma responds to treatment, more than 50% have improvement in neuropathy. In other patients with sensorimotor neuropathies associated with plasma cell dyscrasias, the course is variable, and the M protein may not be related to their neuropathy.

Multifocal Motor Neuropathy and Lewis-Sumner Syndrome

DEFINITION

Multifocal motor neuropathy is characterized by progressive, distal more than proximal, asymmetrical limb weakness, mostly affecting the upper limbs with minimal or no sensory impairment.

EPIDEMIOLOGY

The prevalence of multifocal motor neuropathy is estimated at 2 per 100,000. Men are more frequently affected than women (2.6:1). Initial symptoms develop in 80% between the ages of 20 and 50 years, with a mean age at onset of 40 years. Lewis-Sumner syndrome occurs less frequently than multifocal motor neuropathy.

PATHOBIOLOGY

Multifocal motor neuropathy is considered an autoimmune neuropathy based on its clinical improvement with immunologically based therapies and because of a frequent association with antiglycolipid antibodies. Patients with MMN often have serum antibodies that react with ganglioside GM_1, and these titers decrease during effective treatment. GM_1 is highly represented in neural membranes at the nodes of Ranvier, compact myelin, and the motor end plate at the neuromuscular junction. A blocking effect on mouse distal motor nerve conduction has been induced in vitro by sera from multifocal motor neuropathy patients with and without high anti-GM_1 antibody titers. These data support the presence of serum factors responsible for conduction block in the sera of patients with multifocal motor neuropathy, although these factors are not invariably related to anti-GM_1 antibodies. The Lewis Sumner syndrome, however, is not associated with anti-ganglioside antibodies.

CLINICAL MANIFESTATIONS

The usual pattern is progressive, distal, asymmetrical arm weakness, often in the distribution of a single nerve. In a minority of patients, weakness may start proximally or in the legs. The disease will frequently affect other nerves, occasionally with a crossed distribution (i.e., one arm and the contralateral leg). Asymmetry and predominance of arm weakness may become less evident as the disease progresses. Localized muscle atrophy may be mild or absent in the early stage of the disease but can become prominent later as a result of axonal degeneration.

Fasciculations, cramps, and myokymia occur in patients with multifocal motor neuropathy and those with amyotrophic lateral sclerosis (Chapter 418), making distinction between the two disorders difficult. Marked asymmetry in the degree of clinical findings and electrophysiologic abnormalities between contiguous nerves is suggestive of multifocal motor neuropathy rather than amyotrophic lateral sclerosis. Cranial nerve involvement or respiratory failure as a result of unilateral or bilateral phrenic nerve palsy rarely occurs in multifocal motor neuropathy. The presence of sensory loss suggests Lewis-Sumner syndrome.

DIAGNOSIS

The diagnosis is established by the presence of multifocal, persistent partial conduction blocks on motor but not sensory nerve conduction studies. Lewis-Sumner syndrome has sensory loss as well as weakness, with conduction block in both sensory and motor nerves.

TREATMENT Rx

IVIG (2 g/kg) is the initial treatment of multifocal motor neuropathy, and almost 80% of patients respond within a week. However, improvement is typically brief (3 to 6 weeks), so repeated treatments are required indefinitely. Clinical improvement is often accompanied by a reduction or resolution of the

motor conduction block in some nerves, but it does not consistently correlate with a reduction in antiganglioside antibody titers. Patients may eventually become refractory to IVIG, and another agent may be needed, such as rituximab (e.g., 375 mg/m^2 weekly for four weeks) or azathioprine (2 to 3 mg/kg/day). Plasma exchange and corticosteroids are generally ineffective and have been associated with worsening neuropathy in some patients. Lewis-Sumner syndrome is considered a multifocal variant of CIDP and responds to the same treatments as CIDP.

PARANEOPLASTIC NEUROPATHIES

DEFINITION

Paraneoplastic neuropathies (Chapter 187) are a "remote effect of cancer" not caused by metastatic invasion of neural tissue; radiation therapy or chemotherapy; metabolic, vascular, or hormonal disturbances; or opportunistic infections. It is hypothesized that they are the result of host immune responses to a tumor antigen or antigens that are also present in neural tissues.

EPIDEMIOLOGY

Paraneoplastic syndromes occur in less than 1% of patients with cancer; peripheral neuropathy is only one of the paraneoplastic syndromes. Although more than 25% of patients with cancer have evident neuropathy on neurologic examination, the relationship to malignancy is unclear in most. Paraneoplastic neuropathy may develop before, during, or after the tumor is diagnosed. In certain tumors, neuropathies are distinctive and should prompt a thorough investigation for cancer. Small cell carcinoma of the lung (Chapter 197) is by far the most common underlying neoplasm, followed by carcinoma of the stomach, breast, colon, rectum, ovary, and prostate.

PATHOBIOLOGY

Subacute sensory neuropathy, the most characteristic paraneoplastic neuropathy, results from an immune-mediated ganglionitis that destroys sensory neurons in the dorsal root ganglia. Mononuclear inflammatory infiltrates composed of CD4$^+$ and prominent CD8$^+$ T cells, along with plasma cells, are found in the stroma surrounding the dorsal root ganglion neurons. Other findings include atrophy of the dorsal roots; loss of sensory neurons, which appear to be replaced by a proliferation of satellite cells (Nageotte's nodule); axonal degeneration; and secondary degeneration of the dorsal column of the spinal cord. Inflammatory infiltrates can also be found in peripheral nerves or muscle. Sural nerve biopsies typically reveal only loss of myelinated nerve fibers and are not useful for diagnosis.

CLINICAL MANIFESTATIONS

Subacute sensory neuropathy is characterized by subacute, progressive impairment of all sensory modalities and is associated with severe sensory ataxia and areflexia. Subacute sensory neuropathy may precede the diagnosis of tumor by months or even years.

At onset, patients may have shooting pain and burning sensations. Other symptoms include numbness, tingling, and a progressive sensory loss that may be asymmetrical. Symptoms usually progress rapidly to involve all four limbs, the trunk, and face. Findings may then stabilize, although by this time the patient is often totally disabled. Occasional patients have an indolent course.

Neurologic examination reveals loss of deep tendon reflexes and involvement of all modalities of sensation; large fiber modalities such as vibration and joint position sense are most severely affected. The loss of position sense may lead to severe sensory ataxia with pseudoathetoid movements of the hands and an inability to walk despite normal strength. Cranial nerve involvement may cause sensorineural deafness, loss of taste, and facial numbness. The frequent asymmetrical pattern of symptoms sometimes suggests a radiculopathy or plexopathy.

A paraneoplastic encephalomyelitis characterized by patchy, multifocal neuronal loss in regions of the cerebral hemispheres, the limbic system, the cerebellum, the brain stem, the spinal cord, and autonomic ganglia often develops in patients with subacute sensory neuropathy. Autonomic symptoms include impotence, dry mouth, and constipation.

DIAGNOSIS

The diagnosis is based on recognizing the typical neuropathy in the setting of malignancy. The results of routine laboratory studies are generally normal. The diagnosis is supported by finding serum polyclonal IgG anti-Hu antibodies, also called antineuronal antibodies type 1, or by indirect immunofluorescence or immunohistochemistry and confirmed by Western blot analysis.

Subacute painful, asymmetrical neuropathy or neuronopathy in an elderly patient should prompt a search for carcinoma of the lung because small cell lung cancer (Chapter 197) accounts for more than 80% of the associated tumors. Subacute sensory neuropathy has also been reported in patients with adenocarcinoma of the lung, breast, ovary, stomach, colon, rectum, and prostate as well as Hodgkin's and non-Hodgkin's lymphoma. In patients with no evidence of cancer, detection of anti-Hu antibodies should prompt a computed tomography study of the chest with special attention to the mediastinal lymph nodes. The use of whole body positron emission tomography with fluorodeoxyglucose has been advocated for early diagnosis in patients with anti-Hu antibodies or clinical suspicion of subacute sensory neuropathy because it may reveal neoplastic adenopathy months before computed tomography or magnetic resonance imaging can detect them.

TREATMENT Rx

Subacute sensory neuropathy responds poorly to plasma exchange, IVIG, or various immunosuppressant medications, even when such treatment is started early in the course of the disease, possibly before the loss of sensory neurons. Even successful treatment of the tumor rarely induces remission of subacute sensory neuropathy, but the symptoms may stabilize.

Other Neuropathies Possibly Associated with Cancer

SENSORIMOTOR NEUROPATHY

Sensorimotor neuropathy occurs in approximately 25% of patients with all types of tumors. The neuropathy can have an acute or subacute onset, with a progressive or relapsing remitting course. Because no antineuronal antibody has been specifically associated with these neuropathies, their paraneoplastic nature is not established. Severe or relapsing neuropathies often precede the diagnosis of cancer, but the search for malignancy is generally limited to a chest radiograph, stool samples for blood, and routine blood tests. There are no specific treatments of these neuropathies, and their progression does not necessarily correlate with that of the malignancy.

PARANEOPLASTIC VASCULITIS OF NERVES

A nonsystemic vasculitic neuropathy, which may also involve muscle, occurs with various types of tumor, including small cell lung cancer, lymphoma, and carcinoma of the kidney, stomach, and prostate. Neurologic symptoms may develop either before or after the tumor is diagnosed. The neuropathy is subacute and progressive and usually affects older men. Like many paraneoplastic disorders, these neuropathies often do not respond well to treatment, which is similar to that for the vasculitic neuropathies (see later).

VASCULITIC NEUROPATHIES

DEFINITION

Vasculitic neuropathies (Table 428-5) typically present as painful acute or semiacute axonal mononeuritis multiplex. There is acute motor and sensory loss in multiple nerve territories. The number of nerves involved may be extensive enough to make the distinction between a multifocal and diffuse neuropathy difficult. Occasionally, vasculitic neuropathy can present as sensory neuropathy, trigeminal neuropathy, compressive neuropathy, or autonomic neuropathy. Neuropathy can occur in systemic vasculitis associated with other organ systems as well as in nonsystemic vasculitis affecting just nerve and muscle.

EPIDEMIOLOGY

Systemic vasculitic neuropathy is more common than nonsystemic vasculitic neuropathy. Peak ages at onset of both are the fifth to eighth decades, but vasculitis can occur at any age. Neuropathy, particularly mononeuritis multiplex, is common in several forms of systemic vasculitis. Rheumatoid arthritis (Chapter 272) evolves into systemic rheumatoid vasculitis in 5 to 15% of patients, and vasculitic neuropathy will develop in about 50% of these patients. More than 50% of patients with Churg-Strauss syndrome (Chapter 278), 40 to 50% with Wegener's granulomatosis (Chapter 278), 35 to 75% with polyarteritis nodosa (Chapter 278), and most patients with mixed

TABLE 428-5 SYSTEMIC VASCULITIS AND NEUROPATHY

TYPE	SEROLOGY FEATURES	ASSOCIATED FEATURES	USUAL NEUROPATHY TYPE	NEUROPATHY PREVALENCE
Rheumatoid arthritis	RF 80-90%	Arthralgias, arthritis frequent; multiple organs	Mononeuritis multiplex and sensorimotor neuropathy	50% of patients with vasculitis
Churg-Strauss syndrome	c-ANCA < 30% p-ANCA < 50%	Eosinophilia Asthma	Mononeuritis multiplex	20% of patients
Wegener's granulomatosis	c-ANCA 75-90% p-ANCA < 20%	Pulmonary and renal	Mononeuritis multiplex	15% of patients
Polyarteritis nodosa	c- and p-ANCA rare	Multiple organs, 30% hepatitis B	Mononeuritis multiplex	60% of patients
Mixed cryoglobulinemia	No	Hepatitis C, purpura frequent	Mononeuritis multiplex	20-90% of patients
Sjögren's syndrome	α-Ro/SS-A 60%, α-La/SS-B 50%	Dry eyes, dry mouth; women 90%	Sensory	25% of patients
Systemic lupus erythematosus	ANA screen > 90%	Multiorgan	Sensorimotor neuropathy	5-20% of patients

ANA = antinuclear antigen; p- and c-ANCA = perinuclear and cytoplasmic antineutrophil cytoplasmic antibodies; RF = rheumatoid factor; α-Ro/SS-A and α-La/SS-B = antibodies to the Ro/SS-A and La/SS-B antigens.

cryoglobulinemia (Chapter 193) have neuropathy. Patients with Sjögren's syndrome (Chapter 276) are often initially found to have sensory neuropathies. Neuropathies are uncommon in systemic lupus erythematosus.

PATHOBIOLOGY

In patients with mononeuritis multiplex, axonal degeneration develops as a result of nerve ischemia caused by the vasculitic process. Immune-mediated inflammation and necrosis of blood vessel walls occlude the vessel's lumen, thereby resulting in ischemic damage. Small arteries or arterioles (50 to 300 μm) are most commonly affected, particularly those that occur in watershed areas between the distribution of the major nutrient arteries of proximal nerves. True nerve infarcts are rare.

The immune-mediated inflammation is associated with antibody-antigen complexes that are deposited in the wall of the blood vessel. Antibodies also bind directly to endothelial cell antigens. In both circumstances, complement is activated, as evidenced by deposition of membrane attack complex. Chemotactic factors then recruit neutrophils, which release proteolytic enzymes and generate toxic oxygen free radicals.

The sensory neuropathy of Sjögren's syndrome probably results from the infiltration of dorsal root ganglia by cytotoxic T cells. Some patients with systemic vasculitis have symmetrical neuropathies rather than mononeuritis. The pathogenesis of such cases is not defined.

CLINICAL MANIFESTATIONS

Patients typically have a relatively sudden onset of painful, focal or multifocal weakness or sensory loss. These symptoms reflect ischemia anywhere along the length of the nerve or nerves, generally in the lower extremities. Onset usually occurs rapidly (hours to days) as a result of the abrupt, ischemic etiology.

DIAGNOSIS

Nerve biopsy of clinically affected sensory nerves (sural, superficial peroneal, or superficial radial) is often necessary and is justified because therapy may be aggressive and long-term. Superficial peroneal nerve biopsy may be combined with muscle biopsy from the same incision. Pathologic features diagnostic of vasculitis occur in 60% of patients, and less specific features such as multifocal loss of fibers occur in others. Findings diagnostic of vasculitis include destruction of the vessel and inflammation within the vessel wall. Fibrinoid necrosis, vessel wall scarring, recanalization, neovascularization, and hemosiderin are common, but not essential, histopathologic features of vasculitis.

Although nerve biopsy is the gold standard for diagnosis, clinical, serologic, and electrophysiologic findings can suggest the diagnosis. For example, EMG and nerve conduction velocity studies can distinguish between mononeuritis multiplex and symmetrical neuropathy. It is essential to confirm nerve conduction velocity abnormalities in a nerve before biopsy, which is always required before treatment. An acute or subacute onset of asymmetrical weakness or sensory loss in the distribution of individual nerves suggests mononeuritis multiplex, particularly in the setting of a known connective tissue disorder. Systemic symptoms, such as unexplained weight loss and purpura, or constitutional symptoms, such as fever, myalgias, arthralgias, pulmonary disease, abdominal complaints, rashes, or night sweats, suggest systemic vasculitis in a patient with mononeuritis multiplex.

The erythrocyte sedimentation rate is usually elevated in the systemic vasculitides but is normal in nonsystemic cases. Perinuclear and cytoplasmic antineutrophil cytoplasmic antibody (p-ANCA and c-ANCA) suggests Wegener's granulomatosis (Chapter 278) or Churg-Strauss syndrome (Chapter 278). Hepatitis C (Chapter 151) is usually associated with the presence of cryoglobulins. Serum complement levels, extractable nuclear antigen, angiotensin-converting enzyme levels, serum protein electrophoresis, and HIV serology are generally indicated. CSF analysis is not usually helpful in cases of vasculitic neuropathy but may be needed to exclude infectious (e.g., Lyme disease [Chapter 329]) or other inflammatory causes.

Differential Diagnosis

Acute or subacute mononeuritis multiplex may also result from diabetes, sarcoidosis, Lyme disease, and malignant infiltration of nerves. Multifocal motor neuropathy with conduction block and Lewis-Sumner syndrome can resemble vasculitic mononeuritis multiplex. Sensory neuropathies similar to those in Sjögren's syndrome may occur in patients with diabetes, paraneoplastic syndromes associated with anti-Hu antibodies, and pyridoxine deficiency.

TREATMENT Rx

Systemic Vasculitis

Corticosteroid therapy is used for most vasculitic neuropathies (Chapter 278). Oral prednisone (1 mg/kg) is appropriate for relatively mild cases, but intravenous methylprednisolone (1000 mg/day for 3 to 5 days) may be indicated as initial treatment in severe cases. Daily dosing is commonly used for the first 2 months or longer if the disease remains active. Subsequently, the dose is gradually tapered, with a transition to alternate-day dosing and discontinuation depending on the clinical picture and associated systemic features.

Corticosteroid treatment may be adequate for Churg-Strauss syndrome, but additional medication is generally needed in other forms of systemic vasculitic neuropathy. In most cases of Wegener's granulomatosis and microscopic polyangiitis, combined therapy with glucocorticoids and oral cyclophosphamide (2 mg/kg/day) or weekly oral methotrexate (7.5 mg/week) is used. Azathioprine (2 to 3 mg/kg/day) is also used.

Nonsystemic Vasculitis

Because patients with nonsystemic vasculitic neuropathy may recover spontaneously or have a relatively benign course, low-dose or alternate-day oral prednisone (60 to 80 mg/day) is often adequate therapy. Azathioprine or weekly methotrexate can be used as a glucocorticoid-sparing agent. Doses such as 60 mg of prednisone on alternate days, 2 to 3 mg/kg/day of azathioprine, or 7.5 to 15 mg/week of methotrexate, are reasonable starting doses that can ultimately be tapered if the treatments prove effective.

PROGNOSIS

Most systemic and nonsystemic vasculitis responds to treatment, and patients make at least partial recovery with gradual return of function after a static period. The prognosis of patients with nonsystemic vasculitis is better than that of patients with systemic vasculitis, with fewer episodes of nerve damage; the disease may be monophasic or relapsing remitting over a period of years, and most patients recover the ability to walk.

CRITICAL ILLNESS NEUROPATHY

DEFINITION

Critical illness polyneuropathy is an acute or subacute axonal length-dependent neuropathy that occurs in critically ill patients, not as a direct consequence of their underlying illness. The neuropathy is monophasic and recovers, at least in part, if the patient survives the underlying illness.

EPIDEMIOLOGY

The incidence of critical illness polyneuropathy is uncertain because of variable diagnostic criteria. Moreover, it frequently accompanies critical illness myopathy (Chapter 429), which may be indistinguishable from it. Critical illness polyneuropathy frequently occurs in patients with systemic inflammatory response syndrome (Chapters 106 and 108), a generalized inflammatory host response to severe illness; up to 70% of patients with sepsis have a length-dependent axonal neuropathy.

PATHOBIOLOGY

Nerve biopsies have identified perivascular lymphocytic infiltration, macrophages, and cytokines such as interleukin-1β, interferon-γ, and interleukin-12. Ischemia caused by a sepsis-induced abnormal distribution of capillary blood flow, nutritional deprivation, and hypoglycemia has also been implicated in critical illness polyneuropathy.

CLINICAL MANIFESTATIONS

The typical finding is rapid development of profound limb weakness days to weeks after acquiring a severe illness that necessitated intensive care unit admission and ventilator support. Respiratory muscles are often involved, and inability to wean from the ventilator is a common problem. Elicitable deep tendon reflexes distinguish critical illness polyneuropathy from acute inflammatory demyelinating polyneuropathy. Sensory findings are typically absent, but sensory testing is difficult to perform in severely disabled patients.

DIAGNOSIS

Laboratory studies are rarely helpful. CSF protein is normal, unlike the case with acute inflammatory demyelinating polyneuropathy. A lack of cells also excludes infectious or inflammatory disorders. Creatine kinase levels are normal, unlike critical illness myopathy, in which they may be elevated.

Motor conduction velocities are normal with reduced or absent compound muscle action potential amplitudes. Critical illness polyneuropathy is a predominantly motor disorder, so sensory conduction velocities and sensory nerve action potential amplitudes are normal. Abnormal spontaneous activity from axonal damage may occur within 1 to 3 weeks of onset. The presence of neuropathic and myopathic abnormalities suggests that critical illness polyneuropathy and critical illness myopathy coexist.

Differential Diagnosis

Distinguishing between critical illness myopathy and critical illness polyneuropathy can be difficult. Glucocorticoids and neuromuscular blocking agents predispose to critical illness myopathy (Chapter 429), which occurs in up to 5% of critically ill patients and is also manifested as rapidly progressive weakness of the limbs and diaphragm. Muscle biopsy and special electrical techniques are often needed to diagnose critical illness myopathy. If patients with critical illness myopathy survive their critical illness, their long-term prognosis may be better than that of patients with critical illness polyneuropathy.

Acute inflammatory demyelinating polyneuropathy can mimic critical illness polyneuropathy but can be distinguished by slow nerve conduction velocity and abnormal CSF. Acute motor axonal neuropathy or acute motor and sensory axonal neuropathy may be more difficult to distinguish, particularly if sepsis or another underlying disorder induces an abnormal CSF; nevertheless, the presence of antiganglioside antibodies may help distinguish these disorders from critical illness polyneuropathy. Myasthenia gravis (Chapter 430), botulinum toxin (Chapter 304), acetylcholinesterase inhibitor poisoning (Chapter 110), and other toxins can cause a similar clinical picture.

TREATMENT

Rx

The main treatment is directed at the underlying disease or diseases, such as sepsis. Glucocorticoids and neuromuscular blocking agents should be avoided if possible because both have been associated with critical illness myopathy.

PROGNOSIS

In-hospital mortality has been reported to be as high as 84% in patients with critical illness polyneuropathy, compared with 50% in similarly ill patients without it. Although most patients improve if they survive their underlying illness, up to 10% have persistent severe limb weakness and are ventilator dependent. Most patients have at least some evidence of weakness 2 years after discharge.

DIABETIC AND OTHER METABOLIC NEUROPATHIES

DEFINITION

Diabetic peripheral neuropathies can be separated into two large groups: (1) symmetrical, predominantly sensory or autonomic neuropathies (or both), and (2) asymmetrical mononeuropathies or plexopathies.

EPIDEMIOLOGY

Diabetes (Chapter 236) is the most common cause of neuropathy in the Western world. Diabetic neuropathy occurs in 8 to 70% of patients with diabetes, depending on the criteria used to diagnose neuropathy, and patients with retinopathy or overt albuminuria are more than twice as likely to have neuropathy. Distal symmetrical polyneuropathies are the most common diabetic neuropathy, but distal autonomic neuropathy is also common. For example, impotence develops in 20 to 60% of diabetic men, but widespread autonomic dysfunction develops in less than 5% of diabetic patients.

PATHOBIOLOGY

Distal Symmetrical Polyneuropathy and Autonomic Neuropathy

The pathogenesis of distal symmetrical polyneuropathy and autonomic neuropathy involves both microvascular and metabolic abnormalities, with a causal link between increased blood glucose levels and the development and progression of diabetic neuropathy. The mechanisms by which hyperglycemia causes nerve dysfunction may include activation of the polyol pathway, extensive glycation, altered diacylglycerol and protein kinase activity, and oxidative stress. Evidence from animal models suggests a role for neurotrophic factors, in particular, nerve growth factor, which selectively supports small fiber sensory and sympathetic neurons.

Acute Asymmetrical Neuropathies

The focal nature of these diabetic neuropathies is presumed to result from occlusion of endoneurial arterioles with resultant ischemic damage to the nerve. Changes suggestive of vasculitis are observed in epineurial and perineurial blood vessels in about 50% of cases, and perivascular lymphocytic infiltrates are common.

CLINICAL MANIFESTATIONS

Distal Sensory Polyneuropathy and Autonomic Neuropathy

Distal symmetrical polyneuropathy is typically manifested as insidious symmetrical sensory loss of small (pain and temperature) and large (proprioception) fiber modalities. Paresthesias or painful dysesthesias (e.g., burning or tingling feet) are common, although not invariable. An unsteady gait may be the initial finding. Weakness is usually minimal, even in the distal foot muscles. Ankle reflexes are generally absent, although patellar reflexes may be present. Feet and distal calves are often cold and erythematous. Slow distal proximal progression of sensory symptoms and signs is the rule. By the time that symptoms reach the knees, abnormalities often begin in the hands.

When sensory changes reach the level of the knees, symptoms of autonomic neuropathy often begin: gastroparesis, which may alternate with diarrhea, orthostatic hypotension, anhidrosis, cardiac arrhythmias, and impotence. Autonomic abnormalities can be the most disabling component of diabetic neuropathy.

Acute Asymmetrical Neuropathies

Asymmetrical acute neuropathies cause focal or multifocal symptoms, depending on the peripheral nerve or nerves affected. They are usually accompanied by acute pain in the afflicted region. The pain may be deep and aching or throbbing and lancinating. Most cases of acute focal or multifocal

diabetic neuropathy eventually resolve, at least partially. Pain may resolve within a few months, whereas weakness may take a year or more to recover and may persist. Characteristic manifestations include the following:

1. Compressive *mononeuropathies*. Compressive neuropathies, such as carpal tunnel syndrome, occur more frequently in diabetic patients for unclear reasons. It is not known whether the response of carpal tunnel syndrome to treatment is as effective as when these mononeuropathies occur independently of diabetes.
2. Diabetic *lumbosacral radiculoplexus neuropathy*. Patients are frequently elderly with type 2 diabetes (Chapter 237). Asymmetrical pain in the upper part of the thigh is followed by progressive weakness and atrophy of the proximal leg muscles. Progression to the other leg occurs frequently. In about 50% of those affected, autonomic symptoms also develop, including orthostatic, gastrointestinal, and sexual dysfunction. Weakness may progress for up to 6 months. About 50% of patients require a wheelchair for ambulation, and many require opiates for pain. After the nadir, the patient will usually stabilize for several months, followed by progressive improvement. As many as 50% of patients do not regain full ambulation.
3. *Truncal radiculopathy*. An acute, focal onset of pain and sensory loss develop over a region of the trunk. In extreme cases, the abdominal wall muscles may become weak, resembling a hernia. As with diabetic lumbosacral radiculoplexus neuropathy, at least partial improvement will probably occur after a period of months, but the pain is difficult to control.
4. *Cranial neuropathies*: The classic manifestation is an acute oculomotor nerve palsy in which retro-orbital pain is followed by diplopia and ptosis. Pupillary fibers are often spared, distinguishing the disorder from lesions that compress the oculomotor nerve and cause a dilated pupil. Similar findings may occur with the trochlear (fourth nerve) or abducens nerves. Bell's palsy is more frequent and is less likely to involve taste in diabetic patients than in patients without diabetes.

DIAGNOSIS

Distal Sensory Polyneuropathy

The diagnosis of distal symmetrical polyneuropathy is based on identification of a predominantly sensory length-dependent neuropathy in the presence of either type 1 or type 2 diabetes. Neuropathy can develop independently of good control of blood sugar. Clinically similar neuropathies occur in patients with glucose abnormalities that are detectable only by oral glucose tolerance testing. Nerve conduction studies usually show low-amplitude or nondetectable sensory nerve action potential amplitudes; when detectable, sensory conduction may be slightly slow. Compound muscle action potential amplitudes are often reduced. Motor conduction studies are slightly slowed even if there is only minimal motor involvement clinically. Needle EMG in distal muscles typically demonstrates changes characteristic of chronic denervation. Occasional fibrillations and positive sharp waves may also be present.

Acute Asymmetrical Neuropathy

The focal neuropathies tend to occur in older patients with type 2 diabetes. The characteristic syndromes are diagnosed on the basis of their clinical manifestations and association with diabetes. EMG may demonstrate pronounced denervation in affected muscles. Concomitant evidence of distal symmetrical polyneuropathy is often present clinically and by electrophysiologic studies.

TREATMENT Rx

Distal Symmetrical Polyneuropathy

An important treatment goal in distal symmetrical polyneuropathy is prevention of osteomyelitis and the resultant amputation of toes and feet. Because patients often do not sense injuries to their feet, diligence in foot care is important. Specific treatments to reverse or halt progression of the distal symmetrical polyneuropathy in diabetic patients are not yet available. Current therapy is based on control of hyperglycemia, management of symptoms, and foot care. Careful control of blood glucose (Chapter 236) remains the only treatment proven to delay the onset and slow progression of distal symmetrical polyneuropathy. There is, however, no hemoglobin A_{1c} threshold below which patients avoid risk for neuropathy. For the treatment of pain (Chapter 29), combination therapy of gabapentin (usually starting at about 300 mg three times a day but titrating up to as high as 3600 mg per day) with either nortriptyline (three times a day, titrated to as high as 100 mg per day or as tolerated) or sustained-release morphine (15 mg twice daily) in low doses is effective when less aggressive treatments fail. Pregabalin is effective at doses of 300 mg to 600 mg daily. Duloxetine at 60 to 120 mg daily is another option.

Acute Asymmetrical Neuropathy

Although acute asymmetrical neuropathy generally improves spontaneously, improvement may take months and remain incomplete. Intravenous corticosteroids, IVIG, or plasma exchange may improve the speed and extent of recovery, but these treatments are not of established benefit. Pain management is similar to that just described. Because the pain in patients with diabetic lumbosacral radiculoplexus neuropathy and truncal radiculopathy is focal, topical therapy may be effective.

INFECTIOUS NEUROPATHIES

Neuropathies Associated with HIV Infection

The peripheral nervous system may be involved in all phases of HIV infection (Chapter 401). The most common peripheral neuropathy is a distal, painful, sensory axonal polyneuropathy that is very similar to the toxic neuropathy caused by nucleoside reverse transcriptase inhibitors (NRTIs), including zidovudine, zalcitabine, didanosine, stavudine, and lamivudine. When an iatrogenic neuropathy is suspected, discontinuation of NRTIs may improve symptoms. Conversely, a neuropathy caused by HIV is likely to stabilize or improve with antiretroviral treatment.

Inflammatory neuropathies such as chronic or acute inflammatory demyelinating polyneuropathy can also occur in the early stages of HIV infection; the CSF cytoalbumin dissociation usually seen with these conditions may not be evident in these patients because of a mild CSF mononuclear pleocytosis. The response of these neuropathies to plasma exchange or IVIG is generally good. In later stages of HIV infection, cytomegalovirus (Chapter 384) may cause either an acute lumbosacral polyradiculopathy as a result of direct invasion of nerve roots or a mononeuritis multiplex through a vasculitic mechanism.

Neuropathies Associated with Herpes Zoster

Varicella-zoster virus (Chapter 383) usually remains latent in cranial or spinal ganglia after resolution of a systemic infection. Reactivation, which tends to occur in elderly persons and immunocompromised patients, causes a vesicular skin eruption accompanied by pruritus and dysesthesias. Herpes zoster normally undergoes spontaneous resolution but is frequently followed by a severe post-herpetic neuralgia, which is defined as pain persisting for more than 6 weeks after the rash appears. Early treatment with oral acyclovir (800 mg, five times daily for 7 days) may reduce both the duration of the acute phase and the chance of post-herpetic neuralgia developing, which is usually treated with symptomatic drugs for neuropathic pain (Chapter 29).

The use of concomitant corticosteroids in addition to acyclovir appears to reduce acute pain without exacerbating viral spread. However, corticosteroids do not appear to reduce the incidence or severity of post-herpetic neuralgia.

Neuropathy Associated with Lyme Disease

Borrelia burgdorferi causes a disease with three stages (Chapter 329). In the first stage, shortly after and in the same area of a tick bite, a nonpruritic rash (erythema migrans) appears and spontaneously disappears after a few weeks. The second stage is frequently associated with neurologic complications such as lymphocytic meningitis and focal and multifocal peripheral and cranial neuropathies; characteristic manifestations are unilateral or bilateral facial palsy and radiculitis. The third stage is associated with severe neurologic complications, including encephalopathy, encephalomyelitis, and a predominantly sensory axonal polyneuropathy. A lymphocytic pleocytosis in CSF and demonstration of *B. burgdorferi* infection in serum or CSF are the main laboratory findings. Treatment is discussed in Chapter 329.

Neuropathy Associated with Leprosy

Leprosy (Chapter 334) is the most common cause of peripheral neuropathy in developing countries, although it is infrequent in the Western world. Leprosy may be manifested in different forms, depending on the host's immune system. Patients with normal cell-mediated immunity are more likely to have a tuberculoid form characterized by hypopigmented skin

lesions associated with decreased sensation. In patients with abnormal cell-mediated immunity, the more severe lepromatous form with large disfiguring lesions may develop. A mononeuritis multiplex pattern with prominent superficial sensory loss is the most typical clinical manifestation of leprosy.

If treated early, neuropathies in leprosy can improve significantly. World Health Organization recommendations call for combination therapy that includes dapsone (50 to 100 mg/day or 200 to 250 mg/wk), rifampicin (600 mg monthly), and clofazimine (100 mg/day) (Chapter 334).

Neuropathy Associated with Diphtheria

Although vaccination has made diphtheria (Chapter 300) rare in developed countries, it is still an important cause of subacute neuropathy in developing countries. Some strains of *Corynebacterium diphtheriae* produce a potent neurotoxin that causes palatal weakness, accommodation deficits, and extraocular palsies. This acute manifestation is followed by an ascending paralysis secondary to a demyelinating neuropathy that shares many clinical features with acute inflammatory demyelinating polyneuropathy.

The neuropathy caused by the neurotoxin usually resolves with resolution of the infection. The diphtheria organism can be eradicated by therapy with antibiotics such as erythromycin (2 g/day intravenously divided twice daily for adults) or penicillin (procaine penicillin G, 1.2 million U/day intramuscularly divided twice daily for 14 days). However, the neuropathy, as with other manifestations of the disease, generally requires treatment with diphtheria antitoxin, a hyperimmune antiserum produced in horses. Depending on the severity of the disease, antitoxin is administered intramuscularly or intravenously (80,000 to 120,000 units for extensive disease with a duration of 3 or more days) (Chapter 300).

TOXIC AND DEFICIENCY SYNDROMES

In Western countries, toxic neuropathies are frequently the side effects of medications rather than a result of environmental exposure. In most cases, iatrogenic neuropathy is manifested as a length-dependent or "dying-back" axonal neuropathy. Treatment requires a correct diagnosis (Table 428-6) and discontinuation of the drug, but improvement is often slow and may take several months.

Compressive Neuropathies

Peripheral nerves are vulnerable to chronic compression in many sites: median nerve compression at the wrist within the carpal tunnel (*carpal tunnel syndrome*), median nerve compression in the upper part of the forearm, ulnar nerve compression in the hand (*cubital tunnel syndrome*), ulnar nerve compression at the elbow or wrist, tibial nerve compression behind the medial malleolus (*tarsal tunnel syndrome*), and peroneal nerve compression over the lateral fibular head.

CARPAL TUNNEL SYNDROME

Entrapment of the median nerve at the wrist reflects the limited space available for the median nerve because of the surrounding bone, joint, ligaments, tendons, and synovium. Repetitive motion of the fingers is an exacerbating element. Other precipitating factors include trauma, osteoarthritis, synovial cysts, myxedema (Chapter 233), and amyloid deposition (Chapter 194). Mild symptoms typically involve paresthesias of the first three digits, often occur overnight, and are relieved by shaking or elevating the hands. In more severe disease, objective sensory loss in the median nerve distribution, weakness of median-innervated muscles such as the abductor pollicis brevis, and prolongation of nerve conduction across the carpal tunnel (prolonged distal latency) are characteristic. The diagnosis is supported by identification of *Tinel's sign,* in which tapping the carpal tunnel elicits paresthesias in the median nerve distribution, and by paresthesias produced by sustained flexion of the wrist (*Phalen's sign*). Treatment begins with splinting of the wrist in slight dorsiflexion during sleep. Injection of corticosteroids into the carpal tunnel provides temporary benefit. More severe carpal tunnel syndrome is treated surgically by release of the carpal ligament.[10]

TABLE 428-6 TOXIC AND DEFICIENCY NEUROPATHIES

Associated with antineoplastic agents: vincristine, paclitaxel (Taxol), cisplatin, suramin, thalidomide
Associated with antimicrobials: chloroquine, dapsone, isoniazid, metronidazole, nitrofurantoin
Associated with cardiac medications: amiodarone, perhexiline, hydralazine
Associated with other medications: colchicine, tacrolimus, gold salts, phenytoin, disulfiram (Antabuse), pyridoxine (vitamin B_6)
Associated with heavy metals: lead, arsenic, mercury, thallium
Associated with chemical compounds: acrylamide, carbon disulfide, ethylene glycol, hexacarbons, organophosphate esters, Vacor
Deficiency neuropathies: vitamin B_1 deficiency, vitamin B_{12} deficiency, vitamin E deficiency

Bell's Palsy

Unilateral facial paralysis of acute onset frequently occurs on an idiopathic basis (Bell's palsy). The diagnosis is one of exclusion. Facial nerve palsies also occur in the setting of *herpes zoster oticus* (Chapter 383), in which they are typically associated with otalgia and varicelliform lesions affecting the external ear, ear canal, or tympanic membrane. Facial paralysis of a lower motor neuron type can be caused by carcinomatous meningitis (Chapter 195), sarcoidosis (Chapter 95), Lyme disease (Chapter 329), and HIV infection (Chapter 401).

Primary tumors of the facial nerve can occur with apparently rapidly developing facial paralysis. Facial paralysis can also occur in primary *CNS disease* affecting the pontomedullary junction, such as stroke or multiple sclerosis (Chapter 419).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most cases of facial paralysis are idiopathic. Patients typically notice facial paralysis on inspection in the mirror in the morning. Facial paralysis may be heralded or accompanied by pain behind the ear. The severity of paralysis varies widely.

TREATMENT

Rx

In a randomized trial, 10 days of oral corticosteroids (prednisolone, 25 mg twice daily for 10 days) administered early in the course increased the return of facial function from 63 to 83% at 3 months in patients with idiopathic Bell's palsy;[11] acyclovir added to prednisone is of uncertain benefit.[11] In severe cases, protection of the cornea from drying and injury is essential.

PROGNOSIS

The prognosis is favorable in most cases, but about 10% of patients achieve little recovery. Aberrant regeneration of the facial nerve can cause synkinesias, such as "jaw winking" (when the eye is closed) or tearing accompanying salivation ("syndrome of crocodile tears").

Trigeminal Neuralgia (Tic Douloureux)

Trigeminal neuralgia and other painful cranial neuralgias are discussed in Chapter 405.

429 MUSCLE DISEASES

PATRICK F. CHINNERY

DEFINITION

Muscle diseases, or myopathies, are disorders of skeletal muscle structure or function. Myopathies can be primary and occur in isolation, or they can be part of multisystem diseases that involve other organs.

EPIDEMIOLOGY

Many muscle diseases (Table 429-1) are genetically determined, with an autosomal dominant, autosomal recessive, X-linked, or maternal (mitochondrial) inheritance pattern. Precipitating environmental factors of muscle disease include recent infections, foreign travel, medications such as statins that may increase the likelihood of muscle pain, and alcohol abuse (Chapter 425). Exercise tends to precipitate symptoms in patients with metabolic disorders, whereas cold and damp conditions and a high-carbohydrate meal can precipitate weakness in muscle channelopathies. The prevalence of muscle disease, which is estimated to be 1 per 1000 people, includes acute or short-lived disorders (e.g., myositis owing to infectious or toxic causes; see later), or chronic inflammatory and genetic disorders that cause substantial morbidity over decades. Muscle disease can cause premature death owing to neuromuscular weakness and secondary chest infections or to involvement of other organs in multisystem diseases. Cardiac involvement, which is particularly common in muscle diseases, can cause life-threatening dysrhythmias or chronic heart failure.

PATHOBIOLOGY

The basic unit of motor function is the motor unit, which is defined as the anterior horn cell body, its axon, the neuromuscular junction, and all the skeletal muscle fibers innervated by the one axon. The number of muscle fibers innervated by each motor nerve varies, from a few (e.g., in muscles controlling very precise movements, such as extra-ocular muscle) to more than 1000 (e.g., large and powerful but less precise muscles, such as the quadriceps).

Skeletal muscle fibers are multinucleate giant cells that are the principal component of skeletal muscle. Muscle also contains fibrous connective tissue, blood vessels, and blood components, all of which can be involved in muscle disease. The muscle fiber itself contains interdigitated myofibrils that are composed of thick (myosin) and thin (actin, troponin, tropomyosin) filaments. The myofibrils are organized into a functional unit called the sarcomere, which is about 2 mm in length and is bound by the Z disc. Subcellular organelles between the myofibrils include mitochondria, which are the principal energy source, the endoplasmic reticulum, transverse tubules that communicate with the extracellular space, and vacuoles that contain glycogen and lipid. The muscle cell nuclei are found in the periphery, just below the plasma membrane, which is the sarcolemma.

Muscle function (Fig. 429-1) is dependent on a chemical energy source—adenosine triphosphate (ATP), which in the first 30 minutes of sustained activity is produced by the breakdown of muscle glycogen (glycolysis) and after 30 minutes by fatty acid β-oxidation and oxidative phosphorylation within the mitochondria. Muscle contraction is initiated by the release of calcium from the endoplasmic reticulum and transverse tubules into the sarcoplasm. The calcium binds to troponin, which interacts with tropomyosin and results in actin-myosin binding. The conformational change that results from actin-myosin binding moves the thick filaments relative to the thin filaments, and the Z discs are pulled closer together, thereby leading to muscle contraction in an ATP-dependent process.

The structural integrity of the muscle fiber is maintained by a network of interlinking protein fibers within the muscle, including the cytoskeletal scaffolding protein, titin. These fibers are connected to the sarcomere, to the sarcolemma, and then to the extracellular matrix and connective tissue. Dystrophin anchors the sarcomere to the sarcolemma through its interaction with several glycoproteins called sarcoglycans (α, β, γ, δ), dystroglycans (α, β), and syntrophins (α, β1, β2), which form the dystrophin-sarcoglycan complex that links to the extracellular basal lamina. The basal lamina contains several important proteins that, when abnormal, cause clinical disease, including collagen types I or VI, fibronectin, and laminin, which includes merosin and related proteins.

TABLE 429-1 CLASSIFICATION OF MYOPATHIES

HEREDITARY
Muscular dystrophies
Congenital myopathies
Myotonias and channelopathies
Metabolic myopathies
Mitochondrial myopathies
ACQUIRED
Inflammatory myopathies
Endocrine myopathies
Myopathies associated with systemic illness
Drug-induced/toxic myopathies

CLINICAL MANIFESTATIONS

Muscle diseases are often present with nonspecific symptoms, including fatigue, muscle pain, and generalized weakness. As a consequence, muscle disease is often overlooked in patients with multisystem diseases, or its symptoms are masked by other neurologic or systemic features.

History

Weakness is usually symmetrical. In the legs, proximal weakness causes difficulties in getting out of low chairs or a bathtub or in climbing stairs. Distal weakness can lead to the "flapping feet" characteristic of a bilateral foot drop or to frequent tripping over small objects, such as uneven paving stones or the curb of the sidewalk. In the arms, proximal weakness leads to difficulties with self-care, including washing, brushing the hair, or feeding. Distal hand weakness leads to problems opening jars or bottles, typing at a computer keyboard, or writing. Weakness of the bulbar muscles can lead to swallowing and speech difficulties, neck weakness can lead to a dropped head, and respiratory muscle weakness can lead to symptoms suggestive of nocturnal hypoventilation or respiratory failure.

Fatigue and exercise intolerance can be the presenting features of primary muscle diseases, but they also are common in many systemic and psychiatric disorders. In the absence of objective clinical signs, these symptoms are unlikely to be caused by muscle pathology.

Muscle pain can be difficult to distinguish from joint pain (Chapter 264) or fibromyalgia (Chapter 282). Diffuse, generalized, and persistent muscle pain is rarely due to muscle disease, and sometimes patients describe muscle stiffness as pain. Proximal muscle pain at rest may suggest an underlying inflammatory myopathy, whereas pain precipitated by exercise may suggest a metabolic myopathy. Pain beginning within the first 30 minutes of exercise suggests a disorder of carbohydrate metabolism; symptoms typically are short lived, and further exercise leads to their resolution (the warm-up phenomenon). Muscle pain developing later during exercise suggests a disorder of fatty acid β-oxidation.

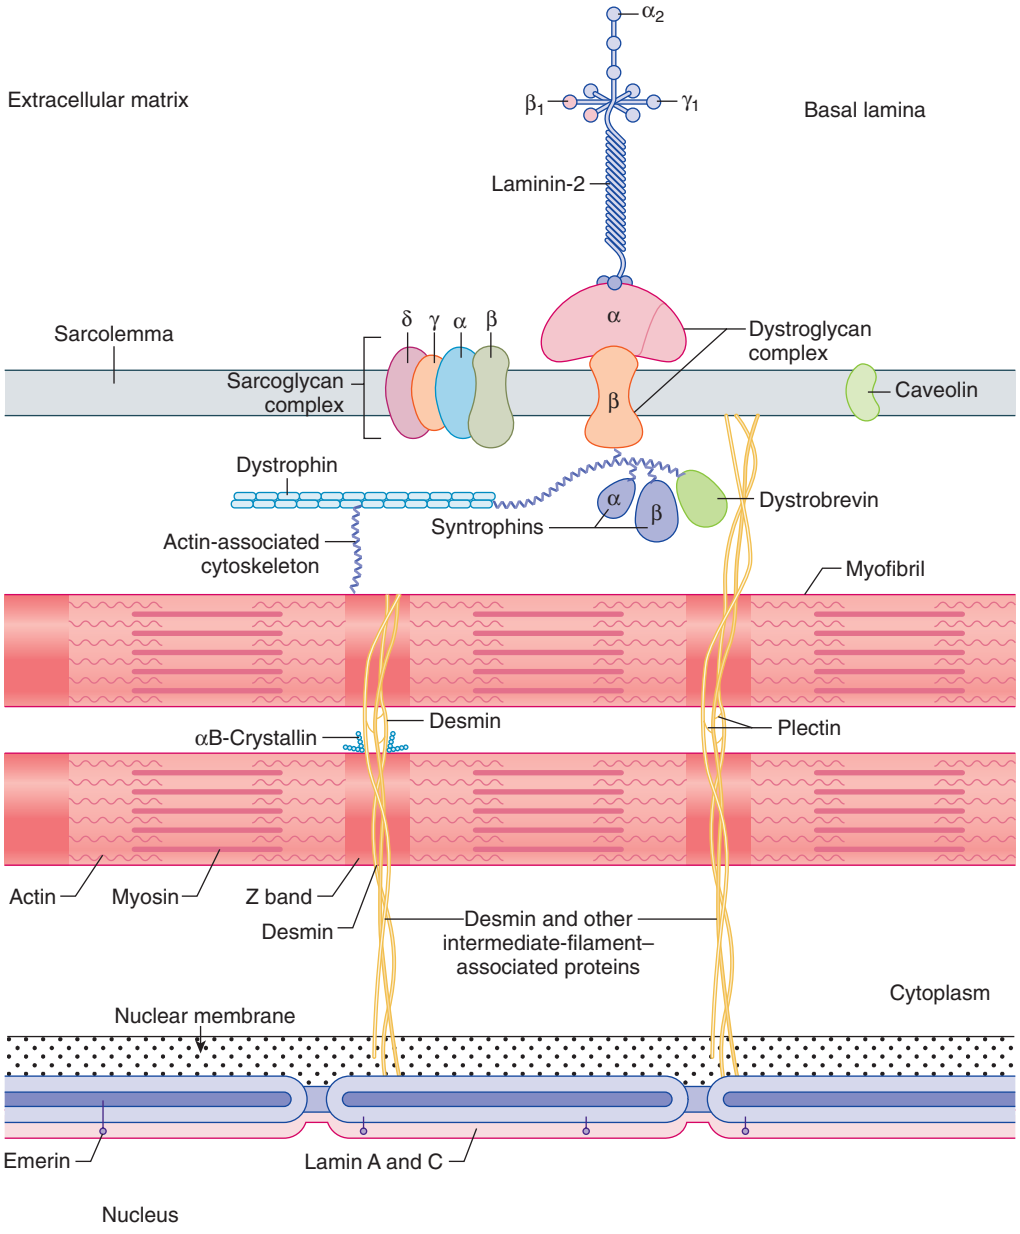

FIGURE 429-1. Muscle structure.

Muscle pain should be distinguished from muscle cramps, which typically affect specific muscles, persist for seconds or minutes, and rarely indicate muscle disease. However, persistent muscle contraction results in contractures, which are particularly seen in the myophosphorylase deficiency of McArdle's disease.

Muscle stiffness, which can be totally subjective and not associated with abnormal muscle fiber contraction, can occur in inflammatory, metabolic, and ion-channel muscle diseases and in nonmuscle diseases such as multiple sclerosis, polymyalgia rheumatica, and connective tissue diseases. Conversely, stiffness associated with weakness or an inability to move the affected muscle suggests myotonia. Myotonia can be painful (paramyotonia), painless, or associated with perceived stiffness if caused by a muscle channelopathy; it can affect limb, facial, or bulbar muscles and lead to persistent limb muscle contraction, eyelid closure, or dysphagia. Patients who describe their hands as "locking" but do not have objective myotonia rarely have a physical explanation for the symptom. Severe acute muscle damage, termed *rhabdomyolysis* (Chapter 115), results in myoglobinuria that presents as dark brown or red urine.

The family history should include questions about muscle diseases as well as systemic illnesses such as heart failure or diabetes that can be the clue to an underlying multisystem mitochondrial disorder.

Physical Examination

A full physical examination is critical to assess for systemic diseases with muscular involvement. The skin also should be evaluated for any signs of systemic disease, including the characteristic heliotrope rash of dermatomyositis (Chapter 277).

The neurologic and motor examinations should help distinguish muscle disease from nerve diseases (Table 429-2). Patients may have facial muscle wasting and weakness, ptosis, or dysmorphic features that lead to an instant diagnosis, such as the characteristic appearance of patients with myotonic dystrophy (Fig. 429-2). Proximal muscle weakness may be evident if patients push themselves up on their thighs or waddle into the consultation room.

Patients should be asked to rise from a low crouched posture and walk on their toes to assess calf muscle weakness or their heels to assess ankle dorsiflexion weakness. The posture should be examined, and the spine should be inspected for evidence of scoliosis. The spine and joints should be moved passively to determine whether there are any contractures, which are usually asymptomatic.

All muscle groups should be inspected for evidence of muscle wasting, hypertrophy, and fasciculation, which is the spontaneous firing of muscle fibers innervated by a single motor unit. Palpation of the large muscles occasionally reveals an unusual texture. The examiner should test for myotonia with both percussion (inability to relax the muscle belly after percussion with a reflex hammer) and grip (inability to relax the fingers from a firm grip).

Muscle strength should be assessed at the bedside (Table 429-3) while distinguishing proximal (limb-girdle), distal (in the legs and arms), axial, neck, orofacial, extraocular, and bulbar muscle weakness. Weakness is usually but not always symmetrical in muscle disease, and specific patterns of weakness can be highly specific for a particular diagnosis.

TABLE 429-2 CLINICAL FINDINGS DIFFERENTIATING MUSCLE FROM NERVE DISEASE

FINDING	MYOPATHY	ANTERIOR HORN CELL DISEASE	PERIPHERAL NEUROPATHY	NEUROMUSCULAR JUNCTION DISEASE
Distribution	Usually proximal, symmetrical	Distal, asymmetrical, and bulbar	Distal, symmetrical	Extraocular, bulbar, proximal limb
Atrophy	Slight early, marked late	Marked early	Moderate	Absent
Fasciculations	Absent	Frequent	Sometimes present	Absent
Reflexes	Lost late	Variable, can be hyperreflexic	Lost early	Normal
Pain	Diffuse in myositis	Absent	Variable, distal when present	Absent
Cramps	Rare	Frequent	Occasional	Absent
Sensory loss	Absent	Absent	Usually present	Absent
Serum creatine kinase	Usually elevated	Occasionally slightly elevated	Normal	Normal

TABLE 429-3 UNITED KINGDOM MEDICAL RESEARCH COUNCIL SCALE

5—Normal power
4—Active movement against gravity and resistance (often subdivided into 4–, 4, and 4+)
3—Active movement against gravity but not against resistance
2—Active movement only possible when gravity has been eliminated
1—Observable muscle contraction, but not capable of initiating movement
0—No contraction

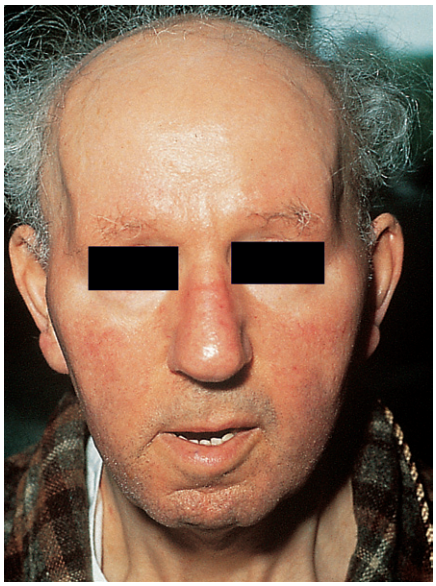

FIGURE 429-2. Myotonic dystrophy in a 50-year-old man. His appearance is typical, with facial weakness, atrophy of the temporal muscles and sternomastoids, and frontal baldness, which gives a monklike appearance. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

TABLE 429-4 GUIDING PRINCIPLES FOR ASSESSING MUSCLE DISEASES

1. **History**
   - Age of onset (most inherited and acquired disorders have a characteristic age of onset)
   - Rate of progression (acute suggests an acquired, often inflammatory cause)
   - Fluctuating weakness (may indicate a neuromuscular junction disorder, metabolic muscle disease, or a channelopathy)
   - Relationship to exercise (may indicate a metabolic myopathy)
   - Muscle pain (may indicate inflammatory or metabolic muscle disease)
   - Relevant multisystem involvement (may indicate a mitochondrial disorder or myotonic dystrophy)
   - Family history (may indicate a genetically determined muscular dystrophy or myopathy)
2. **Pattern of weakness**
   - Limb-girdle weakness is relatively nonspecific.
   - Inherited disorders often have specific patterns of muscle involvement and are usually symmetrical.
   - Fluctuating weakness may indicate a neuromuscular junction disorder, metabolic muscle disease, or a channelopathy.
3. **Testing**
   - The serum creatine kinase may be normal.
   - Electromyography is often normal in metabolic muscle disease.
   - All patients should have an electrocardiogram and echocardiogram to look for cardiomyopathy and/or a conduction defect.
   - Muscle magnetic resonance imaging is increasingly being used to guide the muscle biopsy or reveal diagnostic patterns of muscle involvement.
   - Some inherited muscle diseases can be diagnosed clinically and confirmed by genetic testing without requiring other investigations (e.g., myotonic dystrophy; Duchenne's, facioscapulohumeral, and Becker's muscular dystrophies)
   - Muscle biopsy will reveal the cause in most cases—it identifies specific inflammatory myopathies and muscular dystrophies and often provides diagnostic clues for other muscle and neurogenetic disorders.

DIAGNOSIS

A systematic approach can help guide the diagnosis of muscle diseases (Table 429-4).

Serum Enzymes

The muscle (MM) isoform of creatine kinase (CK) is frequently elevated in patients with muscle disease, although the CK is often normal in metabolic myopathies and in chronic, slowly progressive myopathies. A mild to moderate increase in CK is also seen in patients with acute and subacute neurogenic weakness, including amyotrophic lateral sclerosis (Chapter 418). The degree of CK elevation can be a strong clue for a specific muscle disease in an appropriate clinical context; for example, calf muscle weakness and a very high CK (>1000 I/U) is suggestive of dysferlinopathy, and a CK of more than 20,000 I/U indicates rhabdomyolysis (Chapter 115). Alanine aminotransferase, aspartate aminotransferase, and lactate dehydrogenase levels, which are increased in liver disease (Chapter 148), also can be elevated in muscle disease, but the CK level usually exceeds the upper limit of normal by about ten-fold in muscle disease before these other enzymes can be detected in the plasma.

Neurophysiologic Tests

Nerve conduction studies (see Table 403-5 in Chapter 403), which identify focal or general disturbances of the conduction velocity or amplitude of the nerve impulse, are normal in myopathies. Electromyograms (EMGs) (see Table 403-6 in Chapter 403), together with nerve conduction studies, can distinguish neuropathies and disturbances of the neuromuscular junction from myopathies based on such features as prolonged insertional activity, myotonic discharges, rapid recruitment, and myopathic potentials, which are short amplitude, short duration, and polyphasic. Contractures are electrically silent on EMGs, but muscle cramps are associated with persistent bursts of motor unit activity. EMG changes can be highly focal, particularly in inflammatory myopathies, so the EMG can be normal in patients with muscle disease. Metabolic myopathies also are often associated with a normal EMG.

Imaging

Muscle computed tomography (CT) and magnetic resonance imaging (MRI) can show specific patterns of atrophy and the replacement of muscle

with fat in some inherited myopathies. The MRI can also be used to guide the EMG or muscle biopsy if the pathology is patchy or focal, as in inflammatory myopathy. In specific circumstances, functional MRI is used to investigate suspected metabolic muscle disease, especially mitochondrial disorders.

Muscle Biopsy

Muscle biopsy remains a key investigation for patients with suspected muscle disease, although it has been replaced by molecular genetic analysis in patients with typical Duchenne's or Becker's muscular dystrophy. The biopsy can be the final step in discerning whether limb weakness is neurogenic or myopathic. In addition to the overall appearance, the size distribution of muscle fibers, the degree and distribution of atrophic fibers, the presence of necrosis or inflammatory infiltrates, muscle fiber regeneration, and the replacement of muscle with fat and fibrous connective tissue provide important diagnostic clues.

Molecular Genetic Tests

The widespread availability of molecular genetic testing has had a dramatic impact on the investigation of suspected muscle disease. Disorders that can now be diagnosed with a blood test include Becker's muscular dystrophy and several of the channelopathies. However, given the large number of possible genes, a systematic approach to the investigation of suspected muscle disorders is recommended. Furthermore, molecular diagnosis is currently not possible in some patients, and many of the tests are available only in research laboratories or expensive commercial laboratories.

Other Investigations

Routine hematologic and biochemical tests of liver and kidney function (complete blood count, sedimentation rate, and levels of alanine and aminotransferases, creatine kinase, and creatinine) can assess possible systemic involvement. The erythrocyte sedimentation rate and C-reactive protein level are elevated in inflammatory muscle diseases, and antibody studies (antinuclear antibodies, extractable nuclear antigens, rheumatoid factor, and antineutrophil cytoplasmic antibodies) are useful in patients with suspected autoimmune disorders.

In patients with dermatomyositis (Chapter 277), the evaluation should include an appropriate evaluation for a possible underlying paraneoplastic myopathy (Chapter 187). For patients with suspected metabolic muscle disease, useful screening tests include a fasting blood lactate level in patients with suspected mitochondrial myopathy and a blood acylcarnitine analysis in those with suspected fatty acid β-oxidation disorders.

SPECIFIC MUSCLE DISEASES

Inherited Muscle Diseases

Inherited muscle diseases fall into four main categories: muscular dystrophies (Table 429-5), hereditary myopathies, muscle ion-channel disorders (channelopathies; Table 429-6), and metabolic myopathies (Table 429-7). Some diseases overlap these categories, such as myotonic dystrophy, which includes a characteristic muscular dystrophy, myotonic discharges indicating an ion-channel disorder on EMG, and secondary mitochondrial abnormalities in skeletal muscle suggestive of a metabolic component. Some specific gene defects cause specific phenotypes, now instantly recognizable at the bedside, but other phenotypes are caused by a range of different diseases. A confident clinical diagnosis remains challenging, even in expert hands, so a systematic approach is key to the investigation of these disorders.

Muscular Dystrophies

The term *muscular dystrophy* refers to a pathologic description of muscle fiber degeneration and abnormal muscle regeneration (dystrophy), usually associated with an increase in fat and fibrous connective tissue. From a clinical perspective, muscular dystrophies are a group of genetically determined clinical syndromes with a particular pattern of muscle involvement owing to known or presumed genetic defects. Although the molecular basis of common muscular dystrophies has been defined, new genes are still being identified.

BECKER AND DUCHENNE MUSCULAR DYSTROPHY

Becker and Duchenne muscular dystrophies are both due to mutations in the *DYSTROPHIN* gene, which is located on the X chromosome and determines the amount and structure of the dystrophin protein. Female carriers can develop milder adult-onset disease but can be very difficult to diagnose, especially if there is no family history.

TABLE 429-5 MUSCULAR DYSTROPHIES

X-LINKED
Duchenne's/Becker's (dystrophin)
Emery-Dreifuss (emerin)
LIMB-GIRDLE
Thirteen different autosomal dominant (3) and recessive (10) conditions
CONGENITAL
Autosomal Recesssive with CNS Involvement
Fukuyama's, Walker-Warburg, muscle-eye-brain
Autosomal Recesssive without CNS Involvement

TABLE 429-6 CHANNELOPATHIES AND RELATED DISORDERS

DISORDER	PATTERN OF CLINICAL FEATURES
Thomsen's disease	Myotonia
Becker's disease*	Myotonia and weakness
Paramyotonia congenita	Paramyotonia
Hyperkalemic periodic paralysis	Periodic paralysis with myotonia and paramyotonia
Hypokalemic periodic paralysis	Periodic paralysis
Myotonia fluctuans	Myotonia
Myotonia permanens	Myotonia
Acetazolamide-responsive myotonia	Myotonia
Hypokalemic periodic paralysis	Periodic paralysis
Schwartz-Jampel syndrome (chondrodystrophic myotonia)	Myotonia, dysmorphic
Rippling muscle disease	Muscle mounding/stiffness
Andersen-Tawil syndrome	Periodic paralysis, cardiac arrhythmia, skeletal abnormalities
Brody's disease*	Delayed relaxation, no EMG myotonia
Malignant hyperthermia	Anesthetic-induced delayed relaxation

*Becker's disease, Schwartz-Jampel syndrome, and Brody's disease are autosomal recessive diseases; all other listed diseases have autosomal dominant inheritance.

Duchenne's Muscular Dystrophy

Duchenne's muscular dystrophy affects about 1 in 3500 males. About one third of cases arise from a de novo mutation without a family history. Most patients have a frame-shift mutation in the *DYSTROPHIN* gene with a complete loss of the dystrophin protein. The absence of dystrophin disrupts the mechanical link between the sarcomere and the sarcolemma, probably with a calcium leak that leads to muscle cell necrosis.

TABLE 429-7 METABOLIC AND MITOCHONDRIAL MYOPATHIES

GLYCOGEN METABOLISM DEFICIENCIES
Type II: α-1,4-Glucosidase (acid maltase)
Type III: Debranching
Type IV: Branching
Type V: Phosphorylase (McArdle's disease)*
Type VII: Phosphofructokinase (Tarui's disease)*
Type VIII: Phosphorylase B kinase*
Type IX: Phosphoglycerate kinase*
Type X: Phosphoglycerate mutase*
Type XI: Lactate dehydrogenase*
LIPID METABOLISM DEFICIENCIES
Carnitine palmitoyltransferase*
Primary systemic/muscle carnitine deficiency
Secondary carnitine deficiency
β-Oxidation defects
Medications (valproic acid)
PURINE METABOLISM DEFICIENCIES
Myoadenylate deaminase deficiency*
MITOCHONDRIAL MYOPATHIES
Alpers-Huttenlocher syndrome
Chronic progressive external ophthalmoplegia
Kearns-Sayre syndrome
Pearson's syndrome
Mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes (MELAS)
Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)
Myoclonic epilepsy with ragged-red fibers (MERRF)
Leber's hereditary optic neuropathy
Leigh's syndrome
Infantile myopathy and lactic acidosis

*Deficiency can produce exercise intolerance and myoglobinuria.

CLINICAL MANIFESTATIONS

Duchenne's muscular dystrophy typically presents in young boys between 3 and 5 years of age with delayed motor milestones and proximal muscle weakness. The disorder is relentlessly progressive and causes a cardiomyopathy (Chapter 60) that can result in heart failure and fatal arrhythmias. Mild cognitive impairment is also a feature. By 10 to 12 years of age, most affected individuals are usually confined to a wheelchair. By age 20 years, most patients develop joint contractures and a kyphoscoliosis that lead to respiratory muscle weakness and eventual respiratory failure.

DIAGNOSIS

Affected individuals have a high CK level that is 20- to 100-fold the upper limit of normal from birth. EMG and muscle biopsy are abnormal, with characteristic dystrophic features and reduced size and amount of the protein on immunoblotting studies. However, these investigations are rarely needed to make the diagnosis because the *DYSTROPHIN* gene rearrangement can be detected in blood.

TREATMENT

Rx

Management is largely supportive, including physical therapy to prevent contractures, management of the cardiomyopathy using β-blockers and angiotensin-converting enzyme inhibitors (Chapter 59), and noninvasive ventilation in later stages. Prednisolone (0.75 mg/kg/day) prolongs the period of ambulation and other functions in Duchenne's muscular dystrophy.[1] Creatine (30 mg/kg/day and sometimes higher doses) increases muscle strength and lean body mass.[2] Albuterol is of uncertain benefit, and calcium-channel blockers are not beneficial.

PROGNOSIS

Without ventilating support, patients usually die in their late teens to early 20s. With such support, patients often live well into the third or fourth decades before succumbing to pneumonia, cardiac failure, or gastrointestinal complications.

Becker's Muscular Dystrophy

Becker's muscular dystrophy is a milder form of Duchenne's muscular dystrophy due to a non-frame-shift mutation in the *DYSTROPHIN* gene. It has a similar spectrum of findings but a much wider variation in course of progression.

CLINICAL MANIFESTATIONS

Becker's muscular dystrophy typically presents in boys older than 5 years, teenagers, or even adults with proximal weakness and prominent calf hypertrophy. The clinical course is progressive, and cardiac features are frequent.

DIAGNOSIS

The CK is elevated, although not to the same degree as seen in Duchenne's muscular dystrophy. In about two thirds of patients, a mutation in *DYSTROPHIN* can be detected in blood. The muscle biopsy findings resemble Duchenne's muscular dystrophy but are less dramatic. On immunocytochemistry or on immunoblotting of muscle sections, the amount of the dystrophin protein is decreased.

Female carriers of a *DYSTROPHIN* gene mutation can develop mild symptoms with proximal muscle weakness and an elevated CK in adult life. Diagnosis can be difficult in the absence of a family history, and protein abnormalities are often subtle in the muscle biopsy.

TREATMENT AND PROGNOSIS

Rx

Management is largely supportive. Corticosteroids are rarely used. Careful cardiac monitoring is essential. Heart transplantation (Chapter 82) has been performed in patients with severe restrictive cardiomyopathy (Chapter 60).

Many patients have a normal lifespan, although some develop respiratory failure in middle age and have a shortened lifespan owing to respiratory complications. Heart failure and arrhythmias occur late in the course of disease.

EMERY-DREIFUSS MUSCULAR DYSTROPHY

Emery-Dreifuss muscular dystrophy is due to mutations in the X-chromosomal gene encoding the nuclear membrane protein emerin.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Emery-Dreifuss muscular dystrophy is characterized by progressive joint contractures, scapula-peroneal distribution weakness, and cardiomyopathy with a progressive cardiac conduction disorder.

The CK is often elevated but can be normal. The ECG shows conduction delay. The muscle biopsy shows dystrophic changes, and the protein emerin is deficient on muscle cell nuclear membranes.

TREATMENT AND PROGNOSIS

Rx

Management is supportive, with physical therapy to reduce contractures and cardiac pacing to prevent sudden death due to the conduction defect. Patients usually live many decades with appropriate supportive care.

FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY

Facioscapulohumeral muscular dystrophy, which is an autosomal dominant disorder with variable penetrance, affects about 1 person in 20,000 of the population. It is associated with a deletion of chromosome 4q35 in about 95% of patients, although the responsible gene has yet to be identified.

CLINICAL MANIFESTATIONS

The disease has a highly variable penetrance, ranging from severe proximal facial weakness in early childhood to mild, almost asymptomatic distal weakness presenting in late adult life. Some gene carriers never present clinically. The entire range of phenotypes can be seen in the same family. The muscle weakness affects the face, where it causes difficulty with whistling or smiling, and includes periscapular involvement that leads to scapular winging and to weakness of the shoulder girdle, biceps, and triceps. Distal weakness causes a foot drop, and proximal leg weakness is a late feature. Unlike other muscular dystrophies, muscle involvement is often asymmetrical.

DIAGNOSIS

The CK is usually elevated but can be normal. EMG shows myopathic features. Muscle biopsy shows dystrophic changes occasionally with an inflammatory infiltrate.

TREATMENT AND PROGNOSIS

Rx

Clinical management is supportive, and corticosteroids are of no benefit. Cardiac features are not prominent, and respiratory muscle weakness is a late feature. The prognosis is highly variable, depending on the severity and related age of onset. Many patients have a normal lifespan.

LIMB-GIRDLE MUSCULAR DYSTROPHIES

Limb-girdle dystrophies are a diverse group of genetically determined myopathies caused by defects or deficiencies of muscle proteins, often proteins associated with the muscle cell membrane and particularly the dystrophin-sarcoglycan complex. Although it is possible to identify some specific causes at the bedside, muscle biopsy, immunolabeling studies, and genetic studies are often required to make a precise diagnosis. Each form is rare, and management is largely supportive. The prognosis is usually years to decades after diagnosis.

CONGENITAL MUSCULAR DYSTROPHIES

Congenital muscular dystrophies are a group of rare autosomal recessive muscle diseases that present in childhood with hypotonia (floppy infant) and muscle weakness. The main differential diagnosis is spinal muscular atrophy (Chapter 418), although congenital myasthenia gravis (Chapter 430) also should be considered. Affected infants often have joint contractures, which can be severe at birth. Some congenital myopathies have a pure muscle phenotype, with limited disability and survival well into adult life. Others with central nervous system involvement may be fatal in childhood.

Myotonic Dystrophies

Myotonic muscular dystrophies are the most common inherited muscle diseases. The two main genetic causes, DM1 and DM2, are inherited in an autosomal dominant manner. Both forms cause multisystem disease and can be difficult to distinguish from each other. DM1 is due to an abnormal expansion of CTG nucleotide repeats in a protein kinase gene on chromosome 19. DM2 is due to an abnormal tetranucleotide repeat on chromosome 3.

CLINICAL MANIFESTATIONS

Classic myotonic dystrophy can be diagnosed visually owing to characteristic myopathic facies (see Fig. 429-2), frontal balding in males, nasal speech, and high-steppage gait due to the distal myopathy. Additional features include ptosis, proximal weakness of the neck flexor muscles, especially the sternomastoid, and proximal muscle weakness in later stages. Patients show percussion, grip, and eyelid myotonia (inability to open forcibly closed eyelids). Systemic features include premature posterior subcapsular lens cataracts, testicular atrophy, intellectual impairment, impotence, and hypersomnolence mediated by both central and neuromuscular mechanisms. Diabetes mellitus may develop later in the disease, and dysphagia and constipation are common. Progressive cardiac conduction defects lead to sudden death. Women who transmit DM1 have a high risk of having a child with a severe congenital form.

DIAGNOSIS

The CK may be normal or mildly elevated. EMG reveals myopathic features and myotonic discharges. A muscle biopsy, which is rarely required, will reveal myopathic features. Molecular genetic analysis of the DM1 and DM2 loci usually confirms the diagnosis.

TREATMENT

Rx

All patients should have regular electrocardiogram, echocardiogram, respiratory function, and blood glucose level monitoring and undergo sleep studies to detect nocturnal hypoventilation. Management is largely supportive. Physical therapy can help prevent contractures. Cardiac pacing is frequently required. Hypersomnolence can be treated with overnight positive-pressure ventilation and modafinil (200 to 400 mg daily in the morning) for the central component. Diabetes (Chapter 236) and cataracts (Chapter 431) are managed in the standard manner.

Other Inherited Myopathies

CONGENITAL MYOPATHIES

Congenital myopathies are a group of rare inherited muscle diseases that are generally less severe than congenital muscular dystrophies, both clinically and histopathologically. They often have characteristic morphologic features on the muscle biopsy, present at birth with hypotonia and motor delay, and are slowly progressive. Respiratory muscle weakness is common, and patients can present with ventilator failure at birth or insidiously in adult life.

Central core myopathy, which is a rare autosomal dominant congenital myopathy due to mutations in the ryanodine receptor gene, is associated with malignant hyperthermia (Chapters 427, 440, and 442). *Nemaline myopathies* are a group of diseases with characteristic "nemaline rods" apparent in the muscle biopsy. Different genetic forms have been defined, including mutations in the *NEBULIN, TITIN,* and *α-TROPOMYOSIN* genes. *Myotubular myopathy*, which is an X-linked myopathy defined by the presence of central nuclei within muscle fibers, is due to mutations in the *MYOTUBULARIN* gene. Patients typically have ptosis and ophthalmoplegia.

Myofibrillar myopathies are inherited muscle diseases characterized by the presence of desmin fibrils in the muscle biopsy. Other features in the muscle biopsy include the presence of vacuoles with blue rims and the presence of eosinophilic inclusions. Autosomal dominant or sporadic mutations in *ZASP*, a Z-line association protein, *DESMIN, MYOTILIN,* and *AB-CRYSTALLIN* have been identified. The phenotypes overlap, and patients typically present with very slowly progressive distal muscle weakness that cause a foot drop, pes cavus, and proximal weakness. Cardiomyopathy is common in desmin myopathy.

Other distal myopathies include *Welander's myopathy*, an autosomal disorder that presents with finger extensor weakness and appears to be largely restricted to families of Scandinavian origin. *Tibial muscular dystrophy*, which is an autosomal dominant disorder due to mutations in *TITIN,* presents with bilateral foot drop due to tibialis anterior weakness. *Nonaka myopathy*, which is an autosomal recessive disorder due to mutations in *GNE,* affects the post-translational glycosylation of muscle proteins.

Oculopharyngeal muscular dystrophy is an autosomal dominant inherited disorder due to a triplet repeat expansion of the *PABP2* gene. The disorder typically presents in late life (>50 years of age) with dysphagia and marked ptosis without ophthalmoplegia. Mild distal and proximal weakness occurs later in the disease course. Surgical correction of the ptosis often yields excellent results, but the dysphagia can be difficult to manage. Patients often have a normal lifespan.

Ion-Channel Myopathies

Ion-channel myopathies (see Table 429-6) are genetically determined muscle ion-channel disorders, with specific molecular causes but substantial clinical overlap.

CHLORIDE CHANNELOPATHIES

Autosomal dominant (Thomson's) and autosomal recessive (Becker's) myotonia congenita, which are due to a mutation in the muscle chloride-channel gene *CLC1,* present with painless myotonia, muscle hypertrophy, grip and percussion myotonia, and myotonic discharges on EMG. Patients usually complain that their symptoms get worse in cold and damp conditions and improve with exercise (the warm-up phenomenon). There are usually no cardiac complications. The myotonia responds to mexiletine (150 to 200 mg three times a day). Patients usually have a normal lifespan.

SODIUM CHANNELOPATHIES

Mutations in the voltage-gated sodium-channel gene *SCN4A* cause a range of autosomal dominant phenotypes, including hyperkalemic periodic paralysis, paramyotonia congenital (Eulenburg's disease), and potassium-aggravated myotonia. Periodic paralysis is typically precipitated by sustained exercise, which leads to weakness during the rest period, or by a high carbohydrate meal. The attacks can persist for hours, during which patients can be quadriplegic with no tendon reflexes but normal sensation, normal eye movements, and normal respiration. The serum potassium level may be high during attacks. The physical examination is usually normal between attacks, although later in the disease course, some patients develop fixed proximal weakness associated with tubular aggregates on muscle biopsy. Patients with paramyotonia congenita have myotonia that paradoxically improves with exercise, is often painful, and affects the eyelids. For both phenotypes, avoidance of high carbohydrate loads and treatment with dichlorphenamide (50

to 100 mg twice daily) or acetazolamide (125 to 250 mg three times daily) are effective.

CALCIUM CHANNELOPATHIES

Mutations in the muscle sodium-channel gene *CNA4A* cause hypokalemic periodic paralysis, which is an autosomal dominant disorder that resembles hyperkalemic periodic paralysis, except that the episodes of weakness can persist for up to 24 hours. Avoidance of high carbohydrate loads and treatment with dichlorphenamide■ (50 to 100 mg twice daily) or acetazolamide (125 to 250 mg three times daily) are effective.

OTHER FORMS OF PERIODIC PARALYSIS AND MUSCLE STIFFNESS

Periodic paralysis can occur secondary to a wide range of metabolic and electrolyte disorders (Table 429-8).

Mutations in *KCNJ2* cause *Andersen-Tawil syndrome*, an autosomal dominant periodic paralysis associated with mild distinctive facial features, including hypertelorism and low-set ears, and a propensity to ventricular dysrhythmias. *Brody's disease*, which is an autosomal recessive disorder due to mutations in the SR calcium ATPase gene, is characterized by exercise-induced muscle stiffness that is electrically silent on EMG. *Rippling muscle disease*, which is due to mutations in the *CAVEOLIN3* gene, is characterized by rippling muscles triggered by exercise or percussion.

Neuromyotonia (Isaacs' syndrome) is an autoimmune disorder associated with voltage-gated potassium-channel antibodies and is part of a spectrum of disorders including limbic encephalitis.

Metabolic Myopathies

Metabolic myopathies are caused by enzyme defects that affect the three principal stages of muscle metabolism: (1) carbohydrate disorders due to a defect of glucose-glycogen metabolism; (2) disorders of fatty acid oxidation; and (3) disorders of mitochondrial oxidative phosphorylation. Symptoms can be mild and develop in adult life but can sometimes cause rhabdomyolysis (see Table 429-7).

DISORDERS OF CARBOHYDRATE METABOLISM

Glucose and glycogen are the primary energy source for immediate muscle contraction, so defects of this metabolic pathway cause muscle pain, cramps, contracture, and weakness within the first 30 minutes of exercise, thereby leading to exercise intolerance and muscle deconditioning. Severe episodes are associated with CK levels higher than 1000 I/U, rhabdomyolysis, and myoglobinuria. Most diseases are autosomal recessive, although phosphoglycerate kinase deficiency is X-linked. The most common is McArdle's disease, and the others are extremely rare.

Mcardle's Disease

McArdle's disease (type IV glycogenosis, myophosphorylase), which typically presents with muscle pain or cramps after short bursts of exercise, leads to contractures and exercise intolerance. Some patients present with recurrent rhabdomyolysis. Persistent exercise beyond about 30 minutes leads to the "second wind" phenomenon, when symptoms subside as fatty acids become the primary source of muscle energy. Clinical examination and the CK can be normal between the attacks, although some patients develop fixed proximal muscle weakness with myopathic features on EMG. Histochemical and enzyme analysis of skeletal muscle confirms the diagnosis. Common founder mutations (e.g., R49X) are often found in blood DNA samples. Graded exercise and 75 g of oral sucrose■ before exercise may improve symptoms.

Pompe's Disease

Pompe's disease (type II glycogenosis, α-1,4-glucosidase, or acid-maltase deficiency; Chapter 215) can present in childhood with proximal weakness, hypotonia, and a fatal cardiomyopathy, or in adult life with progressive ventilatory failure. The EMG can reveal myotonic discharges. Abnormal glycogen storage is seen in the muscle biopsy. Enzyme replacement therapy has been shown to be effective in children with the severe form.■ The disorder can be diagnosed by measuring the enzyme activity in leukocytes.

DISORDERS OF FATTY ACID METABOLISM

Fatty acids are the principal source of muscle energy during sustained exercise, especially when the muscle glycogen reserves become exhausted after about 30 minutes of exercise. Fatty acid metabolism involves the transport of fatty acids from the serum into the muscle cell and into mitochondria, where key components of the β-oxidation pathway reside. Both carnitine and carnitine palmitoyltransferase are required to complete this process.

Clinically, disorders of fatty acid metabolism can present with a proximal myopathy, exercise intolerance, muscle pain, and rhabdomyolysis. Cardiomyopathy is an important component of some fatty acid oxidation disorders, and multiorgan metabolic crises, such as hypoketotic hypoglycemia, can occur along with neurologic complications, including a peripheral neuropathy.

Carnitine palmitoyltransferase I deficiency presents in childhood with an encephalopathy and liver failure associated with hypoglycemia and a high blood ammonia during metabolic crises. Despite the similar name, *carnitine palmitoyltransferase II deficiency* presents with muscle pain, exercise intolerance, and myoglobinuria, typically after a long period of fasting or sustained exercise. All standard clinical investigations, including the CK, EMG, and muscle biopsy, can be normal. The measurement of fasting acylcarnitines by tandem mass spectrometry on a dried blood spot is the key to making the diagnosis, and molecular genetic blood tests can detect common mutations in the *CPTII* gene.

Carnitine deficiency can be primary or secondary. Primary carnitine deficiency causes myopathy, cardiomyopathy, and encephalopathy in association with hypoketotic hypoglycemia, although pure muscle presentations have been described. Blood carnitine levels below the laboratory reference range reveal the diagnosis, although prominent fat deposition in muscle is another clue.

Many metabolic myopathies cause a secondary carnitine deficiency, including β-oxidation disorders, disorders of mitochondrial oxidative phosphorylation, and other systemic diseases. The accumulation of lipid within the muscle fibers leads to a lipid storage myopathy. Low carnitine levels can be detected in blood.

TREATMENT Rx

Both primary and secondary carnitine deficiencies respond well to oral carnitine replacement (200 to 400 mg/kg/day in divided doses). Modifying the diet to increase the intake of carbohydrates relative to fat can improve symptoms in carnitine palmitoyltransferase deficiency. Some patients have a multiple acyl-coenzyme A dehydrogenase deficiency (also called trifunctional enzyme deficiency, or glutaric aciduria type II), which responds well to riboflavin (100 mg daily).

DISORDERS OF MITOCHONDRIAL OXIDATIVE PHOSPHORYLATION

Disorders of mitochondrial oxidative phosphorylation (see Table 429-7) are among the most common causes of inherited metabolic disease. They can

present with isolated muscle disease, but often they are multisystemic with cardiac involvement, diabetes mellitus, and both central and peripheral neurological features.

Mitochondria are present in every nucleated cell and are the major source of ATP, which is generated by oxidative phosphorylation, which in turn involves five respiratory chain complexes situated on the inner mitochondrial membrane. Mitochondrial dysfunction results in an energy deficit and, if severe, ultimately leads to organ failure. The genetic basis of mitochondrial disorders is complex because mitochondrial proteins have two genetic origins: mitochondrial DNA (mtDNA), which is maternally inherited, and nuclear DNA. Autosomal dominant, recessive, and X-linked nuclear genetic mitochondrial disorders have been described. Mitochondrial DNA disorders affect the structure or amount of the respiratory chain proteins. Both deletions of mtDNA and point mutations of mtDNA are important causes of disease. Nuclear genetic disorders can affect the proteins, the assembly of the respiratory chain, or the maintenance of mtDNA.

CLINICAL MANIFESTATIONS

Mitochondrial diseases should be considered in all patients with a complex, multisystemic myopathy, especially patients with neuromuscular, ocular, and endocrine involvement. The myopathy is often only a minor feature. Although the list of mitochondrial disorders is extensive, they can be divided into defined clinical syndromes, or ill-defined multisystem disorders.

Mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes is usually due to a specific point mutation of mtDNA (m.3243A>G). Patients can have myopathy, cardiomyopathy, encephalopathy, complicated migraine, seizures, encephalopathy, and attacks superficially resembling stroke. Some patients have one or only a few of these features, some have a more limited phenotype with only diabetes and deafness, and some have an isolated cardiomyopathy.

Myoclonic epilepsy with ragged-red fibers presents with a proximal myopathy associated with slowly progressive degenerative ataxia, epilepsy, myoclonus, and peripheral neuropathy; it is usually caused by a point mutation of mtDNA (m.8344A>G).

Leber hereditary optic neuropathy predominantly affects young adult males who have a history of subacute bilateral visual failure affecting both eyes within 2 to 3 months; more than 95% of cases have mtDNA point mutations in m.3460G>A, m.11778G>A, or m.14484T>C.

Chronic progressive external ophthalmoplegia with ptosis and the gradual limitation of eye movements is seen in up to 20% of mitochondrial disorders. About 95% of patients have sporadic mtDNA point mutations or deletions, but the disease can also be inherited as either an autosomal dominant or recessive trait. This disease can occur in isolation, with a proximal myopathy, or with ataxia, diabetes, deafness, and cardiac conduction block (Kearns-Sayre syndrome).

Mitochondrial disorders in children are invariably severe and result in premature death as a result of subacute necrotizing encephalomyopathy (*Leigh's syndrome*), hepatorenal failure (*mtDNA depletion syndromes*), cardiomyopathy, and severe lactic acidosis. Children with *Pearson's syndrome*, caused by the accumulation of mtDNA deletions, typically present with pancytopenia, sideroblastic anemia, and exocrine pancreatic failure. *Primary coenzyme Q10 (ubiquinone) deficiency* is a rare recessive disorder that can present with myoglobinuria and myopathy in childhood, or with ataxia and seizures in adult life.

DIAGNOSIS, TREATMENT, AND PROGNOSIS Rx

The investigation of suspected mitochondrial disorders involves a systematic screen for multisystem complications, especially diabetes and cardiomyopathy; muscle biopsy to look for histochemical cytochrome *c* oxidase deficiency or biochemical evidence of respiratory chain dysfunction; and molecular genetic tests. Some primary mtDNA defects are not detectable in blood, so skeletal muscle is often required for the genetic tests. For example, the diagnosis of ubiquinone deficiency can be made by measuring coenzyme Q10 in muscle.

Vitamins and cofactors, including thiamine, riboflavin, and ubiquinone (coenzyme Q10), have shown varying degrees of benefit in individual cases. Management is largely supportive, with surveillance and treatment of complications. Prognosis varies depending on the phenotype, ranging from the relatively normal life expectancy with chronic external ophthalmoplegia to a relatively rapid demise with Leigh's syndrome.

OTHER METABOLIC AND TOXIC MYOPATHIES

Myopathy can complicate many metabolic disorders, including hypothyroidism (Chapter 233), Addison's disease (Chapter 234), Conn's syndrome, hyperparathyroidism (Chapter 253), vitamin D deficiency (Chapter 252), and liver and renal failure (Chapters 132 and 157). The myopathy is often subtle, the CK level and EMG are often normal, and the muscle biopsy may be nonspecifically abnormal.

Many drugs cause myopathies (Table 429-9) with proximal muscle weakness, muscle pain, and exercise intolerance. The CK and EMG can be normal, and muscle biopsy findings may be nonspecific. Often the diagnosis is reached only after removal of the toxic agent leads to a resolution of symptoms. Statins can cause muscle pain and, rarely, myoglobinuria.

INFLAMMATORY MUSCLE DISEASES

Inflammatory myopathies are a heterogeneous group of acquired muscle diseases (Table 429-10). Most patients present with muscle weakness, with or without pain, and exercise intolerance. Most patients have an elevated CK, abnormal EMG, abnormal muscle MRI, and an inflammatory infiltrate on muscle biopsy. However, the inflammatory process can be patchy and missed

on the EMG and the muscle biopsy. Similarly, a short period of corticosteroid treatment can mask the findings.

Inclusion body myositis is the most common inflammatory myopathy presenting in men older than 50 years. It typically begins insidiously with proximal weakness and then evolves to affect the quadriceps, the long finger flexors in the arms, and the tibialis anterior, where it results in a foot drop. The signs are often asymmetrical. Bulbar and respiratory muscle weakness occur later in the disease course, which is usually refractory to immunomodulatory therapy. No treatment has been proved to influence the disease's slow progression, with significant disability resulting within 5 years.

Polymyositis, Dermatomyositis, and Other Inflammatory Myopathies

Polymyositis and dermatomyositis are covered in Chapter 277. Systemic lupus erythematosus (Chapter 274), mixed connective tissue disease (Chapter 278), Sjögren's syndrome (Chapter 276), and rheumatoid arthritis (Chapter 272) can cause an inflammatory myopathy, as can sarcoidosis (Chapter 95). Systemic viral illnesses frequently cause muscle pain and an elevated CK, which are rarely a major clinical concern. Other microorganisms also cause myositis (Table 429-11), which rarely dominates the clinical picture.

DISORDERS OF NEUROMUSCULAR TRANSMISSION

ANGELA VINCENT AND AMELIA EVOLI

DEFINITION

Neuromuscular transmission depends on the release of acetylcholine from synaptic vesicles that are stored in the terminal boutons of the motor nerve axon (Fig. 430-1). Invasion of the motor nerve terminal by the action potential opens voltage-gated calcium channels, resulting in the Ca^{2+}-dependent

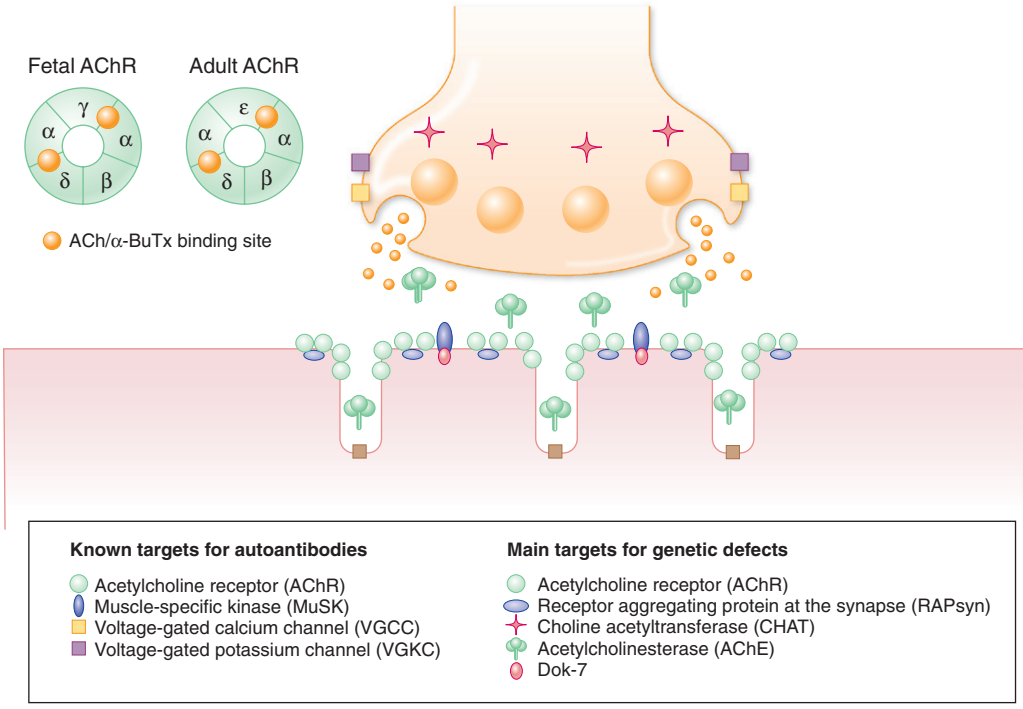

FIGURE 430-1. Diagrammatic representation of the neuromuscular junction, indicating the ion channels, receptors, enzymes, and associated proteins that are the most frequent targets for autoimmune diseases *(left)* or mutations in genetic diseases *(right)*. The acetylcholine receptor exists in fetal and adult isoforms as illustrated at *top left*. The replacement of the fetal form by the adult form takes place toward the end of gestation in humans. Voltage-gated sodium channels are located at the bottom of the postsynaptic folds.

release of the vesicular contents into the synaptic space. Acetylcholine binds to the acetylcholine-gated ion channels (acetylcholine receptors [AChRs]) on the postsynaptic membrane, thereby leading to the opening of these channels and a local depolarization, the end plate potential. If the end plate potential exceeds the critical firing threshold, voltage-gated sodium channels (sited at the bottom of the postsynaptic folds) open to generate the muscle action potential that propagates along the muscle fiber and activates muscle contraction. The action of acetylcholine is terminated by its dissociation from the AChRs, which close spontaneously after 1 to 4 milliseconds; hydrolysis of acetylcholine by acetylcholinesterase; and acetylcholine diffusion from the synaptic cleft. Meanwhile, in the motor nerve terminal, the voltage-gated calcium channels close spontaneously, and the resting membrane potential is restored through the transient opening of voltage-gated potassium channels.

The extent to which the amplitude of the end plate potential exceeds the threshold for activation of the voltage-gated sodium channels is called the safety factor. In healthy individuals, the amplitude decreases during repeated activity but does not fall below this threshold; thus, neuromuscular transmission is not compromised. However, if there is a an abnormally low end plate potential amplitude, failure of neuromuscular transmission may occur. Causes include defects in the release of acetylcholine, the postsynaptic response to acetylcholine, or the number or sensitivity of the voltage-gated sodium channels. Morphologic changes to the presynaptic or postsynaptic components or to the basal lamina between them may also influence the efficacy of transmission. Although myasthenia gravis and some neurotoxic envenomations (Chapter 113) are the most common disorders of neuromuscular transmission, a number of conditions have been implicated (Table 430-1).

AUTOIMMUNE DISEASES

Myasthenia Gravis

EPIDEMIOLOGY

Myasthenia is the most common disorder of neuromuscular transmission, with a prevalence of about 15 per 100,000 in Western countries. All races can be affected. It can occur at any age from about year 1 onward, with a small peak in the third decade. It also increasingly is being recognized at later ages, with an annual incidence rising above 5 per 100,000 in individuals older than 70 years, in whom it is important to differentiate from other causes of limb or bulbar muscle weakness.

Myasthenia gravis itself is heterogeneous and can be divided into different subtypes; the relative frequency of these different forms is not known, but relatively mild childhood forms are frequent in some Asian countries. Neonatal myasthenia gravis, due to the placental transfer of maternal antibodies to the AChR or to the muscle-specific kinase, affects up to one in eight babies born to mothers with myasthenia gravis. Autoimmune myasthenia gravis must be distinguished from congenital myasthenic syndromes, which are caused by gene mutations.

PATHOBIOLOGY

Pathophysiology

Myasthenia gravis is the result of a defect in neuromuscular transmission. The postsynaptic response to acetylcholine, the end plate potential, is reduced so that the threshold for activation of the muscle action potential is not reached. At a severely affected end plate, this deficiency can occur at the initiation of contraction, but it is most common during repetitive activity when the end plate potential naturally declines. This phenomenon, occurring across many end plates within a muscle, is responsible for the decrement in the amplitude of the compound muscle action potential on repetitive nerve stimulation, a finding that is diagnostic of a disorder of neuromuscular transmission.

In myasthenia gravis, the reduced end plate potentials result from loss of functional AChRs on the postsynaptic membrane and also from morphologic damage to the membrane. This damage leads to loss of AChR-containing membrane and to simplification of the postsynaptic folds, which contain the voltage-gated sodium channels. The result is a raised threshold for generation of the action potential, thereby further compromising neuromuscular transmission. In most patients, these changes are caused by antibodies against the AChRs. The pathophysiology in patients without such antibodies, including patients with muscle-specific kinase antibodies, is not well studied.

Like most synapses, the neuromuscular junction is highly regulated. If the nerve is cut, leading to loss of neuromuscular transmission, the muscle responds by upregulating the expression of AChR that revert to a fetal phenotype (see Fig. 430-1). Alternatively, if the activity of the postsynaptic muscle decreases, the motor nerve attempts to compensate. Consequently, in myasthenia gravis, there is some increase in the release of acetylcholine from the motor nerve and an increase in the synthesis of AChRs in the muscle fiber.

Pathogenesis

Myasthenia gravis is an antibody-mediated autoimmune disease that is associated with other autoimmune diseases, most often thyroid disease, and, in younger patients, with an increased incidence of the human leukocyte antigen (HLA)-B8 and -DR3 haplotype that also is associated with several other autoimmune diseases. Anti-AChR antibodies act by three main mechanisms (Fig. 430-2). First, a few antibodies directly inhibit the binding of

TABLE 430-1 DISORDERS OF NEUROMUSCULAR TRANSMISSION

DISEASE	TARGET	PATHOBIOLOGY
AUTOIMMUNE		
Myasthenia gravis	AChRs	Antibodies to AChR in 85% reduce AChR numbers and EPP amplitude Antibodies to MuSK in 5-10%—mechanism not clear
Transient neonatal myasthenia	AChRs, MuSK	Maternal antibodies cause transient disease in neonate; not seen commonly if mother receiving treatment
Arthrogryposis	Fetal AChR	Maternal antibodies that inhibit fetal AChR function paralyze baby in utero, leading to joint contractures; very rare cause of arthrogryposis
Lambert-Eaton myasthenic syndrome	VGCCs	Antibodies to VGCC in 90% reduce VGCC numbers and ACh release and EPP amplitude
Acquired neuromyotonia	VGKCs	Antibodies to VGKCs in 40% lead to increased and spontaneous ACh release
GENETIC		
Acetylcholine receptor deficiency	AChR	Recessive mutations in AChR-subunit genes cause reduced AChR expression
Acetylcholine receptor deficiency		Recessive mutations in *RAPSYN* cause reduced anchoring of AChR on the postsynaptic membrane, or in *DOK-7* causing a synaptopathy
AChR kinetic abnormalities	AChR	Dominant or recessive mutations in AChR-subunit genes cause kinetic defects—"slow" and "fast" channel syndromes
Choline acetyltransferase deficiency	Choline acetyltransferase	Recessive mutations in the gene for choline acetyltransferase (*CHAT*) cause reduced ACh release
Acetylcholine esterase deficiency	AChE	Recessive mutations in the collagen tail (*COLQ*) that anchors AChE at the neuromuscular junction cause absence of AChE
Arthrogryposis, multiple pterygium, Escobar's syndrome	Can occur with rapsyn, δ- or γ-subunit AChR mutations	Fetal akinesia
NEUROTOXIC		
Botulism	Presynaptic ACh release	Botulinum toxin gains entry into the presynaptic motor nerve and cleaves proteins involved in ACh release mechanism
Envenomation following bites from snakes, spiders, scorpions, etc.	Varied sites of action	Neurotoxins specific for VGCCs, VGKCs, AChE, AChRs, voltage-gated sodium channels, and other targets are frequent in many animal venoms and generally inhibit function
Drugs and insecticides	Varied sites of action	Muscle relaxants and other drugs Many antibiotics and quinine-related drugs can alter neuromuscular transmission at high dose Organophosphates block AChE and have complicated acute and chronic actions

AChE = acetylcholinesterase; AChR = acetylcholine receptor; EPP = end plate potential; MuSK = muscle-specific kinase; VGCC = voltage-gated calcium channel; VGKC = voltage-gated potassium channel.

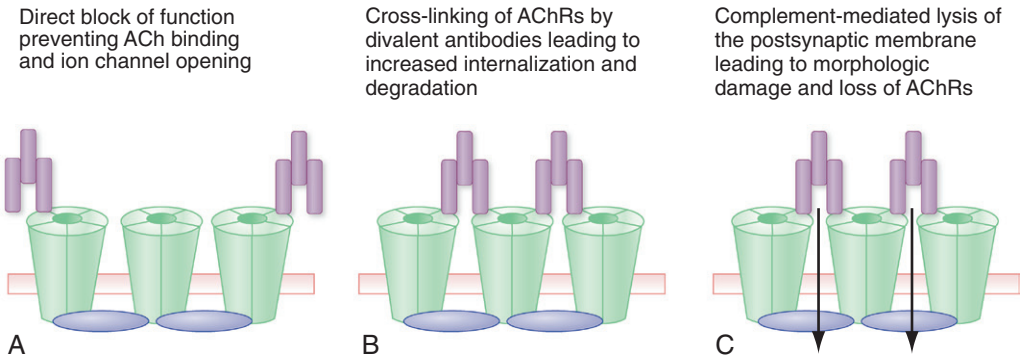

FIGURE 430-2. Mechanisms of loss of the acetylcholine receptor (AChR) at the neuromuscular junction. Antibodies can act (**A**) by directly blocking ACh binding or ion channel function; (**B**) by cross-linking the AChRs in the membrane, thereby leading to increased internalization and degradation; or (**C**) by complement-dependent lysis of the AChR-containing postsynaptic membrane. In myasthenia gravis, complement-dependent lysis is likely to be the most important mechanism overall. Interestingly, there is no evidence of complement-dependent mechanisms in either the Lambert-Eaton myasthenic syndrome or acquired neuromyotonia, in which cross-linking of the respective ion channels with increased internalization seems to be the main mechanism.

acetylcholine to the AChR and cause a pharmacologic-like blockade of function. Second, because of their divalence, antibodies can bind simultaneously to two adjacent AChRs, through the α-subunits that are present in duplicate in each receptor, to form AChR-antibody complexes that are internalized and degraded by the muscle fiber, thereby leading to loss of AChRs. Third, most of the antibodies are immunoglobulin G1 (IgG1) subclass, a subclass that binds and activates complement. As a result, the membrane attack complex is activated, leading to destruction of the postsynaptic membrane and probably causing the morphologic damage that is frequently seen. All these effects are strictly limited to the neuromuscular junction; the remainder of the muscle fiber is essentially normal.

The AChR antibodies are IgG, have high affinity, and are highly specific for the native human AChR. Although the antibodies are the effector mechanism for the loss of AChRs, their characteristics indicate that specific antibody production requires helper T cells that can recognize AChR epitopes. The thymus gland, which is often abnormal in myasthenia, is at least one site where the immune response occurs. In early-onset myasthenia gravis, the thymus is often "hyperplastic," with numerous T- and B-cell lymphocytic infiltrates in the medulla. These infiltrates are very similar to the germinal centers found in lymph nodes, and some contain B cells that express surface immunoglobulin specific for AChRs. Plasma cells are also present and synthesize AChR antibodies. In the thymic medulla, muscle-like "myoid" cells have AChRs on their surface in both normal and myasthenic individuals; these cells probably provide the antigenic stimulus responsible for the germinal center formation and AChR antibody production in myasthenia gravis.

In late-onset myasthenia gravis, the thymus is mostly normal for age. In patients without AChR antibodies, the thymus gland is more likely to appear normal for age, particularly in patients with muscle-specific kinase antibodies. However, in patients without either AChR or muscle-specific kinase antibodies, a typical thymic hyperplasia is often present.

Thymoma

Thymoma occurs in about 10% of myasthenic patients, reaching a peak in middle age. Thymomas are epithelial cell tumors and correspond mainly to the World Health Organization types B1 and B2. The epithelial cells attract large numbers of T lymphocytes, which may be sensitized to the AChR in the tumor and then exported to the periphery. Rarely, myasthenia gravis arises after removal of a thymoma.

CLINICAL MANIFESTATIONS

Myasthenia gravis presents clinically with painless muscle weakness that increases with muscle use and improves after rest. In many patients, the weakness starts in the eye muscles, where it results in double vision and ptosis (drooping eyelids). In others, it may first affect bulbar muscles or limb muscles (Fig. 430-3). Virtually any skeletal muscle may be involved as the illness progresses. Typically, the weakness varies in distribution and severity from day to day or from week to week, and it is often worse in the evening. It may first appear following an infection. Established weakness can increase with anxiety, with infection, or with the menstrual period and tends to improve with rest.

Ptosis, which is often asymmetrical, and diplopia initially can be transient and first noticed while driving, for example. Severity can range from mild unilateral ptosis or minimal diplopia to profound bilateral ptosis, which obscures vision, combined with almost complete ophthalmoplegia. Bulbar symptoms include weakness of facial muscles with difficulties in closing eyes and a "snarling" smile, difficulty in chewing, nasal or slurred speech that can noticeably deteriorate as speech continues, impaired swallowing sometimes associated with nasal regurgitation of fluids, reduced tongue movements, and head droop related to neck weakness.

Limb muscle involvement is common, and proximal muscles are usually more involved than distal. Proximal weakness of the legs can lead to collapse when walking and can be misinterpreted as a functional (psychogenic) disorder. Weakness of elbow extension and of finger abduction may be prominent. By contrast, ankle dorsiflexion is rarely affected except in severe disease.

Respiratory muscle involvement is less common but can be life threatening, especially if associated with dysphagia. Selective involvement of the diaphragm can cause severe breathlessness in the supine posture. Wasting is uncommon but can affect the facial muscles and tongue, for example, in long-standing disease. Tendon reflexes are typically brisk. Bladder disturbances are rare, and sensory symptoms do not occur.

Subtypes of Myasthenia Gravis

Several subgroups can be distinguished on the basis of clinical and pathologic criteria and can help to inform treatment.

FIGURE 430-3. Marked ocular and facial muscle weakness in a young female with myasthenia gravis.

Ocular Myasthenia Gravis

Ocular myasthenia gravis is confined to extraocular muscles; if it remains localized for at least 2 years, subsequent generalized weakness is unlikely. AChR antibody levels are generally low and are undetectable in about 50% of patients. This subgroup rarely is associated with a thymoma. The neuromuscular junction of ocular muscles shows structural and physiologic differences from typical limb muscles. Ocular weakness is often the presenting symptom not only in myasthenia gravis but also in neurotoxin poisoning, for example, botulism (Chapter 304). Thus, physiologic factors or accessibility of the neuromuscular junctions of ocular muscles to circulating factors may make them particularly vulnerable to antibodies in myasthenia gravis.

Generalized Myasthenia Gravis with Acetylcholine Receptor Antibodies

Among patients with generalized disease and AChR antibodies, there are three clinical subgroups. Early-onset myasthenia gravis is more frequent in females and associates strongly with HLA-A1, -B8, and -DR3. The thymus is generally hyperplastic. AChR antibody titers are usually high and decline to varying degrees after successful treatments, including thymectomy.

Late-onset myasthenia gravis is becoming increasingly common with the aging of the population and, when associated with bulbar weakness, may be mistaken for amyotrophic lateral sclerosis (Chapter 418) or brain stem cerebrovascular disease. Among older patients, males are more frequently affected, and the thymus is usually normal for age.

Thymoma-associated myasthenia gravis is an important distinction because thymectomy or other specific tumor therapy is required. Most patients with thymomas and myasthenia gravis present between the ages of 30 and 60 years.

Generalized Myasthenia Gravis with Muscle-Specific Kinase Antibodies

About 15% of myasthenic patients with generalized symptoms do not have detectable AChR antibodies. A variable proportion of these patients have antibodies to another neuromuscular junction protein, the muscle-specific kinase. Muscle-specific kinase antibodies are mainly IgG4 and are absent or very infrequent in patients with AChR antibody–positive myasthenia gravis, patients with persistent ocular myasthenia gravis, and patients with thymoma. Muscle-specific kinase antibodies are found more often in younger females, including children, with marked ocular, bulbar, neck, or respiratory muscle weakness but are seen less frequently in older patients. It is not yet clear how these antibodies cause the neuromuscular junction defect.

Generalized Myasthenia Gravis with Neither Acetylcholine Receptor nor Muscle-Specific Kinase Antibodies

Some patients with generalized myasthenia gravis have neither AChR nor muscle-specific kinase antibodies. These patients can develop severe disease but usually respond well to treatment and may have low-affinity antibodies to AChR.

DIAGNOSIS

Diagnosis is based on the clinical features, serologic testing for specific antibodies, clinical electrophysiology, and, if doubt still remains or specialized facilities are not available, the clinical response to anticholinesterase medication (Table 430-2). Mediastinal imaging is needed to exclude a thymoma in patients with AChR antibodies.

AChR antibodies are present in about 85% of patients with generalized symptoms but in only 50% of patients with purely ocular involvement. In the absence of AChR antibodies, especially in subjects with generalized symptoms, testing for muscle-specific kinase antibodies is recommended. Both AChR and muscle-specific kinase antibodies are very specific, and their detection in symptomatic patients confirms the diagnosis.

The electrophysiologic abnormality is an abnormally large decrement (>10%) in the amplitude of the compound muscle action potential on low-rate (3-Hz) stimulation with increased jitter or blocking on single-fiber electromyogram (EMG). In patients with muscle-specific kinase antibodies, EMG abnormalities may be detectable only in facial muscles. These EMG changes are not specific for myasthenia gravis but can occur in any disorder that interferes with neuromuscular transmission.

Intravenous administration of edrophonium (Tensilon), a short-acting cholinesterase inhibitor, transiently improves myasthenic weakness but requires an appropriate medical setting, including resuscitative facilities and

AChE = acetylcholinesterase; AChR = acetylcholine receptor; BoTx = botulism; ChAT = choline acetyltransferase; CMS = congenital myasthenic syndromes; Dok-7 = downstream of kinase 7; LEMS = Lambert-Eaton myasthenic syndrome; MG = myasthenia gravis; MM = mitochondrial myopathy; MuSK = muscle-specific kinase; SCS = slow channel syndrome; seroneg = seronegative for AChR and MuSK antibodies.

the availability of atropine, because of the risk for adverse events and severe cholinergic reactions, including syncope. A test dose of 2 mg is given intravenously, followed 30 seconds later by 6 to 8 mg if no adverse event has occurred. The equivalent doses in children are a 20 µg/kg test dose followed by 60 to 80 µg/kg. Some patients improve sufficiently with the test dose that it is not necessary to give the full dose. An alternative pharmacologic test in adults is a single dose of subcutaneous or intramuscular neostigmine (1 to 2.5 mg) or of oral pyridostigmine (60 mg).

Differential Diagnosis

Congenital AChR deficiency syndromes (see later) should be considered in patients who have clinical and EMG evidence of myasthenia but are seronegative for AChR and muscle-specific kinase antibodies. Lambert-Eaton myasthenic syndrome almost always begins with difficulty in walking; ocular symptoms are rare, and specific laboratory tests are available (see later). The ocular muscle involvement that characterizes Miller-Fisher syndrome is more rapid in onset than is usual in myasthenia gravis and is associated with GQ1b antibodies. Mitochondrial myopathy may show signs that are similar to those of myasthenia gravis (e.g., asymmetrical ptosis and limitation of eye movements), and there may be increased jitter on single-fiber EMG, but this condition and oculopharyngeal dystrophy can be distinguished from myasthenia gravis by the nonfluctuating weakness and by muscle biopsy. In neurasthenia and chronic fatigue syndrome (Chapter 282), the laboratory tests for myasthenia gravis are negative.

TREATMENT Rx

Most patients with AChR antibodies respond to oral pyridostigmine, 30 to 60 mg four or five times daily; in patients with mild disease, this dose may adequately control symptoms. Doses in excess of 90 mg are likely to cause gastrointestinal side effects, abdominal cramps and diarrhea, which can be controlled with oral propantheline bromide, 15 mg, or loperamide, 2 mg. Patients with muscle-specific kinase antibodies generally show an unsatisfactory response to pyridostigmine. In some of these patients, pyridostigmine, even at a low doses, can increase weakness and cause nicotinic side effects (muscle cramps and diffuse fasciculations).

Neonatal Myasthenia Gravis

Pyridostigmine, 3 to 5 mg, can be given every 4 hours to about an hour before a feeding. Close monitoring and respiratory support in a special unit may be required.

Ocular Myasthenia

Diplopia can sometimes be helped by the use of prisms. Ocular symptoms that respond incompletely to pyridostigmine are often improved or completely corrected by low-dose prednisone therapy (e.g., 5 mg every other day) increasing by 5 mg at weekly intervals either until symptoms are completely controlled or until a ceiling dose (e.g., 1 mg/kg) is reached. When remission is established, the dose can be slowly reduced (e.g., by 5 mg at 2-weekly intervals) until symptoms recur and then adjusted upward to define the effective minimal dose. Full withdrawal of prednisone is usually followed by a symptomatic relapse. Most centers do not recommend thymectomy for nonthymomatous ocular myasthenia gravis. In patients who fail to respond adequately to prednisone or who are intolerant of the medication, the addition of azathioprine (2 to 2.5 mg/kg body weight) or ocular muscle surgery is an option. However, the diagnosis should be reviewed in patients who show no improvement with high-dose prednisone treatment.

Thymoma

Thymoma usually represents an absolute indication for surgery, but removal of the tumor typically does not result in improvement in muscle weakness. If the tumor is found to be locally invasive, postoperative radiotherapy is indicated. If tumor spread is more extensive, chemotherapy is performed, mainly with cisplatin-containing regimens.

Generalized Nonthymomatous Myasthenia Gravis

When generalized symptoms are inadequately controlled by pyridostigmine, thymectomy is often recommended empirically even for patients without a thymoma, especially patients younger than 45 years. Despite the absence of trials and no clear consensus from observational data, thymectomy in early-onset patients with anti-AChR antibodies appears to be associated with an increased rate of remission. By comparison, thymectomy does not appear to influence the course of the disease in patients who have anti-MuSK antibodies and in whom the thymus is generally devoid of hyperplastic changes. Most patients respond to alternate-day prednisone, started at a low dose (e.g., 10 mg every other day) and increasing by 5 to 10 mg per dose to 1.0 to 1.5 mg/kg. Because starting prednisone can temporarily exacerbate the disease, patients are usually best managed in the hospital, especially if they have bulbar or respiratory muscle involvement. When remission is established, the dose can be reduced by 5 to 10 mg every 2 weeks (or more slowly) until symptoms recur, when it can then be adjusted upward, aiming to define the effective minimal dose. Prophylactic treatment for steroid-induced bone disease should be considered in all patients (Chapter 251).

For chronic treatment, immunosuppressive medication is required in patients who do not respond satisfactorily to prednisone or need high maintenance doses. Because these agents have a long latency of effect, they are generally combined with prednisone (see earlier) during the early phases of treatment and then used as monotherapy if steroids can be withdrawn or are contraindicated. Azathioprine (2.5 mg/kg/day) is the preferred treatment;

compared with prednisone alone, combination treatment is better tolerated and associated with fewer relapses.[A] Cyclosporine (3 to 5 mg/kg daily) is effective as monotherapy or combined with steroids[B] and is frequently used as the second-choice immunosuppressant. Although the efficacy of mycophenolate mofetil in association with prednisone is questioned,[B] this agent at the standard dose of 2000 mg/day is used in patients who are unresponsive to or intolerant of azathioprine. Tacrolimus is also used when the other agents fail or cannot be tolerated. Methotrexate (5 to 15 mg weekly) is an option for those intolerant of azathioprine, but long-term randomized studies are not yet available. When remission has been achieved, doses can be reduced slowly and cautiously; full withdrawal is likely to be followed by relapse.

Immunoglobulin infusion[B] and plasmapheresis are equally efficacious[B] for providing short-term improvement, typically persisting 4 to 6 weeks, and can be used to prepare patients for thymectomy, to cover the initiation of prednisone therapy, or to control an exacerbation of myasthenic weakness. An immunoglobulin infusion of 1 g/kg given on day 1 only is as effective as 1 g/kg given on day 1 and again on day 2.[B] Because of the short-lived benefits of these therapies, they must be accompanied by additional immunosuppressive therapy, as noted previously.

Inhibition of the production of acetylcholinesterase using a short antisense oligonucleotide was both effective and safe in a phase Ib study on patients with anti-AChR positive MG. Rituximab, a monoclonal anti-CD20 antibody that markedly reduces circulating B cells, has been used successfully in patients with refractory disease.

PROGNOSIS

The increasing use of immunologic therapies, coupled with advances in critical care, has improved the prognosis in nonthymomatous myasthenia gravis. Many patients can expect substantial improvement or remission with a normal life expectancy. The prognosis is less good, however, in those with invasive thymoma.

Lambert-Eaton Myasthenic Syndrome

DEFINITION AND EPIDEMIOLOGY

The Lambert-Eaton myasthenic syndrome, which is a rare disorder that can occur in paraneoplastic (Chapter 187) and nonparaneoplastic forms, affects all races. The incidence of the paraneoplastic form is much higher, but its shorter survival results in a similar prevalence of the two types. The paraneoplastic form affects about 2% of patients with small cell lung cancer (Chapter 197) and can also occur with lymphoma (Chapter 191). The nonparaneoplastic form associates with HLA-A1, -B8, and -DR3, as in myasthenia gravis.

PATHOBIOLOGY

Lambert-Eaton myasthenic syndrome is an antibody-mediated presynaptic disorder characterized by a reduced number of acetylcholine quanta (vesicles) released by each nerve impulse. End plate potentials recorded from intercostal muscle biopsies are consequently much reduced in amplitude. During repetitive high-frequency nerve stimulation, the end plate potential amplitude increases, probably because build-up of calcium in the motor nerve terminal leads to increased release of acetylcholine. Freeze-fracture electron microscopic studies of motor nerve terminals show that the "active zone" particles, which represent voltage-gated calcium channels, are reduced in number and disorganized. IgG binds to the presynaptic nerve terminal at the sites of acetylcholine release. The antibodies in Lambert-Eaton myasthenic syndrome appear to act principally by cross-linking the voltage-gated calcium channels on the surface of the presynaptic motor nerve membrane, thereby leading to their clustering and internalization. The antibodies also interfere with transmitter release from postganglionic parasympathetic and sympathetic neurons in injected mice, providing an explanation for the autonomic dysfunction observed in many patients.

CLINICAL MANIFESTATIONS

Almost all patients present with difficulty in walking, which exhibits a rolling characteristic. Weakness in ocular, bulbar, and respiratory muscles is less common than in myasthenia gravis. Weakness predominantly affects proximal muscles, which may show augmentation of strength during the first few seconds of a maximal contraction. Reflexes are absent or depressed but can increase after 10 seconds of maximal contraction of the muscle (post-tetanic potentiation). Autonomic symptoms such as dry mouth, constipation, and erectile dysfunction are present in most patients. Cerebellar ataxia occasionally may be present. Patients with nonparaneoplastic Lambert-Eaton myasthenic syndrome may have other autoimmune diseases, notably vitiligo.

DIAGNOSIS

Diagnosis is based on the clinical features, on a positive serum voltage-gated calcium-channel antibody test, and on the characteristic EMG findings (see Table 430-2). Antibodies specific for the α1A (P/Q) subtype of voltage-gated calcium channels are found in 90% of patients, both with and without small cell lung cancer. Patients may not respond convincingly to intravenous edrophonium. On EMG, the amplitude of the resting compound muscle action potential is reduced, but it increases by more than 100% after 10 seconds of voluntary contraction of the muscle or during high-frequency (40-Hz) nerve stimulation. Chest imaging is required in those at risk for tumor.

Differential Diagnosis

Botulinum poisoning (Chapter 304) causes blockade of presynaptic transmitter release at the neuromuscular junction as well as EMG changes similar to those in the Lambert-Eaton myasthenic syndrome. Botulism is detected by finding the toxin in serum or the *Clostridium botulinum* bacteria in the wound or feces. Myopathies (Chapters 277 and 429) can mimic Lambert-Eaton myasthenic syndrome clinically, but autonomic changes do not occur, EMG findings are different, and muscle biopsy is abnormal.

TREATMENT

Rx

Plasma exchange leads to clinical improvement within a few days in acutely ill patients, and most patients respond to immunosuppressive drugs or intravenous immunoglobulin therapy. Intravenous immunoglobulin therapy (1 g/kg for 2 days) improves strength, with an associated decline in specific antibody.[B] Specific tumor treatments (resection, local radiotherapy, chemotherapy) often lead to improvement of the neurologic disorder. Most patients respond to 3,4-diaminopyridine (10 to 20 mg four times daily).[B] This drug is available in Europe and many other countries; it has yet been approved by the U.S. Food and Drug Administration but can be obtained through some referral centers. Long-term immunosuppressive treatment with prednisone, azathioprine, or cyclosporine may be required in those with severe weakness, using doses similar to those described previously for myasthenia gravis.

PROGNOSIS

Prognosis mainly depends on the association with malignancy. Patients with paraneoplastic Lambert-Eaton myasthenic syndrome tend to have a progressive disease and a less satisfactory response to treatment. The nonparaneoplastic disease responds generally well to therapy as described previously.

ACQUIRED NEUROMYOTONIA

DEFINITION AND EPIDEMIOLOGY

Neuromyotonia, or Isaacs' syndrome, is a rare disorder primarily characterized by myokymia (spontaneous undulating muscle contractions) that can be intermittent or continuous and may be present during sleep or general anesthesia. It results from the hyperexcitability of motor nerves. A milder variant, the cramp-fasciculation syndrome, is more common.

PATHOBIOLOGY

Neuromyotonia may be associated with other autoimmune diseases or other autoantibodies, and cerebrospinal fluid analysis may show oligoclonal bands. In about 15% of patients, it is paraneoplastic, usually associated with thymoma and occasionally with lung cancer. Occasionally, neuromyotonia appears to be triggered by infection or allergic reactions, and it may improve spontaneously within weeks to months in these cases.

CLINICAL MANIFESTATIONS

The clinical presentation is heterogeneous with a combination of muscle stiffness, cramps, myokymia (visible undulation of the muscle), pseudomyotonia (e.g., failure to relax after fist clenching), and weakness. Increased sweating is common. Myokymia persists during sleep. Cramp-fasciculation syndrome shares some features with neuromyotonia. Some patients have sensory symptoms, including paresthesias, dysesthesia, and numbness, and a few have autonomic such as constipation or cardiac irregularities and central nervous system features of an encephalopathy, including insomnia, hallucinations, delusions, and mood change (Morvan's syndrome).

DIAGNOSIS

EMG shows spontaneous motor unit discharges that occur as distinctive doublet, triplet, or multiplet bursts with high intraburst frequency (40 to 300 per second), longer continuous bursts, and postactivation contraction. The abnormal muscle activity may be generated at different sites throughout the length of the nerve, but in most cases it is principally distal. Antibodies to voltage-gated potassium channels are found in 40% of patients. The differential diagnosis includes neuromyotonia caused by acquired and inherited neuropathies and by voltage-gated potassium-channel gene mutations (Kv1.1) that can associate with neuromyotonia and episodic ataxia.

TREATMENT AND PROGNOSIS Rx

Neuromyotonia can be improved by anticonvulsant drugs, such as carbamazepine (up to 800 to 1000 mg daily), phenytoin (up to 300 mg daily), or lamotrigine (up to 100 mg daily), that downregulate sodium channel function, thereby reducing the hyperexcitability of nerves. Plasma exchange and intravenous immunoglobulins, using the same regimen as for myasthenia gravis, may be followed by short-term improvement. Immunosuppressive medications, again using the same drugs as for myasthenia gravis, are effective in some patients. Neuromyotonia is often a monophasic disease that can be successfully managed with symptomatic and immunodulating treatment. Because it is commonly associated with myasthenia gravis, the administration of pyridostigmine can increase symptoms of motor nerve hyperexcitability. Prognosis is less favorable in cases with central nervous system involvement.

GENETIC MYASTHENIC SYNDROMES

Congenital myasthenic syndromes (see Table 430-1) are inherited disorders that result from mutations in genes encoding key proteins at the neuromuscular junction. In the United Kingdom, their prevalence is at least 6 per 1 million population.

PATHOBIOLOGY

The genetic mutations can be presynaptic, synaptic, or postsynaptic and can involve many of the genes specific for neuromuscular junction proteins. The most common is the AChR ε-subunit gene, in which the single nucleotide missense substitutions or frameshift mutations usually result in complete loss of function of the AChR ε-subunit. Because this subunit replaces the AChR γ-subunit around the time of birth, the babies are normal in development but show weakness during late pregnancy and in the neonatal period. Survival probably depends on the continued expression of the γ-subunit. AChR deficiency can also result from defects in the gene for rapsyn, a cytoplasmic protein required for the clustering of the AChRs at the neuromuscular junction. Single nucleotide changes in genes for any of the AChR subunits can affect acetylcholine-induced receptor channel openings, leading to kinetic defects. In the fast channel syndrome (recessive), the result is reduced function of AChR, whereas in the slow channel syndrome (dominant), the channel opens for prolonged periods, thereby resulting in subsynaptic accumulation of ions and degenerative changes.

Mutations in the *COLQ* gene, which gives rise to the collagen tail that anchors acetylcholinesterase in the synaptic cleft, are less common. The resulting continuous exposure of the postsynaptic membrane to acetylcholine leads to degenerative changes and progressive muscle weakness. Mutations in choline acetyltransferase, the enzyme responsible for the synthesis of acetylcholine, do not always lead to dysfunction at rest; during repetitive activity, however, the amount of acetylcholine in each packet decreases, with consequent failure of neuromuscular transmission. Mutations in *DOK7* cause a "synaptopathy" with small, simplified neuromuscular junctions. Dok-7 binds muscle-specific kinase, and the mutations are thought to impair the signaling that maintains the synaptic structure. Other gene mutations are rarely identified.

CLINICAL MANIFESTATIONS

Clinical manifestations may vary from death in utero in severe cases to mild symptoms that present in adulthood. Although most cases present in infancy with ptosis, hypotonia, and difficulties with feeding and breathing, the slightly different patterns of muscle weakness provide clues that point to which gene is involved. Arthrogryposis multiplex congenita, indicative of fetal akinesia, often associates with rapsyn mutations. Life-threatening episodic apneas can occur with mutations in choline acetyltransferase or rapsyn or in fast-channel syndromes. Severe ophthalmoplegia occurs in endplate acetylcholinesterase deficiency, AChR deficiency due to AChR subunit mutations, and fast channel syndromes, but is rarely seen in the other genetic syndromes. Motor symptoms with *DOK7* mutations usually appear at about 2 years of age after the child first learns to walk and are characterized by a limb-girdle proximal pattern of muscle weakness.

DIAGNOSIS

The EMG findings in the AChR deficiencies and fast channel syndromes are similar to those in typical myasthenia gravis. In the slow channel syndrome and acetylcholinesterase deficiency syndrome, there may be a double response to a single nerve stimulus (see Table 430-2). Most patients show a response to cholinesterase inhibitors (edrophonium or neostigmine), with the exception of the slow channel syndrome, acetylcholinesterase deficiency, and Dok-7 congenital myasthenic syndromes. DNA screening is essential. Genetic analysis can confirm the diagnosis and help in treatment, prognosis, and counseling, although the faulty gene has not been identified in many families.

The principal differential diagnoses are spinal muscular atrophy, infant botulism, hereditary neuropathies, and congenital myopathies or muscular dystrophies. Onset in early childhood, adolescence, or adulthood, as can occasionally occur, may mean that the genetic nature of the disorder is not recognized or initially leads to the incorrect diagnosis of seronegative myasthenia gravis.

TREATMENT AND PROGNOSIS Rx

Many of the congenital myasthenic syndromes respond to acetylcholinesterase inhibitors, as used for myasthenia gravis, and to 3,4-diaminopyridine (1 mg/kg/day in four divided doses). For the slow channel syndrome, some patients have responded to fluoxetine (60 to 100 mg/day in adults), but the use of fluoxetine in children or adolescents requires psychiatric supervision. For syndromes in which the neuromuscular junction is destabilized or there are degenerative changes, such as for Dok-7 or end plate acetylcholinesterase deficiency, treatment with ephedrine (75 to 100 mg/day in adults, 3 mg/kg/day in children) or salbutamol (0.5 to 2 mg, three times a day when ephedrine is not available) can be remarkably effective. The beneficial effects of this treatment are not seen immediately but build up over a period of 6 months or more.

Although these congenital disorders can be fatal during infancy, usually because of apneic episodes during infections, most tend to be nonprogressive and stable or even may improve during adolescence or adult life. The exceptions are the slow channel syndrome and acetylcholinesterase deficiency, which, owing to the excess AChR activations that they cause, can be associated with progressive degenerative changes at the neuromuscular junction, although this risk is largely mitigated with treatment.

431 DISEASES OF THE VISUAL SYSTEM

MYRON YANOFF AND DOUGLAS CAMERON

The eye is a compact, complicated structure (Fig. 431-1) that is remarkably stable throughout life. Once the growth of the eye is complete, at about the age of 3 years, the structure of the eye changes very little for the next 60 to 80 years.

The eyelids physically protect the eye. The visual axis contains blood vessel–free structures, including the tear film, cornea, intraocular aqueous, crystalline lens, vitreous, and retina that, except for the crystalline lens, remain essentially transparent throughout life. Delicate intraocular structures are protected by a tough collagenous "eye wall" composed of the cornea and sclera. The optic nerve is formed from retinal ganglion cell axons and the continuation of the brain dura, arachnoid, and pia maters. The optic nerve is long enough to allow free excursions of the eye through a 100-degree arc under the influence of six coordinated and critically placed rectus muscles. All these functional components are housed in a bony cavity, the orbit, which protects the eye from external injury.

The eyelid skin, only loosely connected to underlying structures, is among the thinnest of the body. The eyelid is unique because it contains the highest density of sebaceous glands in the body. These meibomian glands produce a sebaceous (lipid) material that is the principal evaporation retardant for the tear film. Malorientation of the eyelid margin or malorientation of the cilia (trichiasis) may cause extensive scarring to the anterior surface of the cornea, even to the point of blindness. The eyelid is opened under the influence of the levator muscle. The tendon of the levator tends to degenerate over time to produce mechanical ptosis. The soft tissue of the eyelid is separated from the soft tissue of the orbit by the orbital septum, a major collagenous barrier to protect orbital soft tissue from extension of eyelid inflammation. Extension of inflammation from preseptal cellulitis or ethmoiditis may cause septic optic neuropathy. Involution of elastic tissue supporting the skin of the anterior eyelid is reduced over time, causing dermatochalasis ("baggy eyelids"). The redundant tissue may be sufficient in quantity to restrict visual field, particularly superiorly.

The conjunctiva is a mucous membrane covered by stratified, nonkeratinizing squamous epithelium containing goblet cells. The epithelium is supported by delicate fibrovascular tissue that contains lymphatic channels. Squamous cell carcinoma or malignant melanoma originating in the conjunctiva may extend through these channels to regional lymph nodes or beyond. The conjunctival epithelium contains melanocytes. Immune processing cells are present in the epithelium (Langhans cells) and in the stroma in the forms of collections of non-nodal B and T lymphocytes. Non-nodal primary lymphomas, which tend to have an indolent course in this location, may arise from this tissue. The aqueous portion of tears is formed constantly by accessory lacrimal glands in the conjunctiva and lid soft tissue and by reflex action from the lacrimal gland. Symptoms of itching and burning, as well as periodic disturbance of vision, may result from decreased tearing.

Tears drain through puncta at the nasal eyelid margin to the nasolacrimal duct that exits inferior to the inferior turbinate of the nasal cavity. The epithelium of the nasolacrimal duct also contains melanocytes and is supported by a resting lymphocyte population. Neoplasms including lymphoma, concretions (dacryoliths), and tissue injury from trauma may occlude the puncta in adults.

The cornea is avascular and lined both anteriorly and posteriorly by surface cells. Lack of an adequate tear film, called dry eye syndrome, may seriously alter the ability of the cornea to transmit light, thereby affecting visual acuity. The posterior cellular lining of the cornea is a single layer of highly modified corneal endothelial cells. Lack of effective pumping by the endothelial cells will allow excess hydration of the corneal stroma, seen clinically as corneal edema. The corneal stroma is particularly sensitive to proteolysis from collagenases found with certain inflammatory diseases such as herpes simplex keratitis. The result is progressive corneal thinning and possible perforation of the cornea with multiple recurrent episodes of herpes simplex keratitis.

The intraocular pressure is measured by indentation tomography. The amount of pressure necessary to flatten the central cornea is proportional to the intraocular pressure.

The anterior chamber is bounded by the posterior surface of the cornea, the anterior surface of the iris, and the anterior crystalline lens within the pupillary space. Aqueous material normally flows from the posterior chamber into the anterior chamber through the pupil and exits into the general circulation through the trabecular meshwork. Most causes of pathologically increased intraocular pressure and optic nerve damage, that is, glaucoma, are due to abnormalities of filtration through the trabecular meshwork. The posterior chamber is bounded by the posterior surface of the iris, the ciliary body circumferentially, and the anterior surface of the vitreous. The crystalline lens is located entirely in the posterior chamber.

The anterior segment is composed of the cornea and the anterior and posterior chambers. Most of the anterior segment is derived from the skin. The posterior segment is the remainder of the eye. Most of the posterior segment structures are derived from the central nervous system.

When first formed, the crystalline lens is a totally cellular structure bounded by a true basement membrane. Throughout life, the new cells that are continuously added from the outer layer epithelial cells compress the central cells, thereby resulting in cell degeneration in the central core (nucleus). The lens doubles in volume from birth to age 70 years at the cost of both pliability (presbyopia) and clarity (cataract). The lens is suspended in the posterior chamber by fibers (zonules) attached to the ciliary body.

The ciliary body is the posterior extent of the iris. Its surface cells produce aqueous, and its muscles function in accommodation.

The vitreous is composed mostly of water and type II collagen. The vitreous makes up the majority of the volume and weight of the eye. It functions as a biochemical sink as well as to maintain neural retinal attachment. With time, the vitreous shrinks and separates from the retina (posterior vitreous detachment). Condensed and displaced vitreous casts a shadow on the retina, which is perceived by the patient as "floaters."

The retina is the site of photochemical conversion of light to electrical energy. Ganglion cells and their axons in the internal retina aggregate at the optic disc to form the optic nerve. Only the inner half of the retina is supplied by the retinal circulation. The outer half of the retina is supplied by a large-caliber capillary lake in the choroid (the choriocapillaris). Only a 500-μm area of the posterior retina, the central macula (about 3 to 5% of the total retina), has the ability to resolve images to 20/20. The remainder of the retina has much less sensitive image resolution. Extensive biochemical support and control of stray light are performed by the retinal pigment epithelium located between the choriocapillaris and the photoreceptor outer segments. The blood-retinal barrier, which protects the biochemical integrity of the retina, is composed of anatomic attachments between neighboring retinal pigment epithelial cells, as well as attachments between vascular endothelial cells of the retinal circulation. The retina is held in place by physiologic forces that may be compromised by holes forming in the retina (rhegmatogenous retinal detachment) or by fluid accumulating in the subretinal space (serous retinal detachment).

The optic nerve is composed of approximately 1 million axons from retinal ganglion cells. Axons are separated into bundles by pial septa, which are in turn enclosed in an arachnoid layer. The dura is contiguous with the posterior sclera and the periosteum of the optic canal. The optic nerve is supplied by delicate vessels extending from the dura across the arachnoid to the pial septa. The central retinal artery is present in the axial layer of the optic nerve near the eye but does not supply blood to the optic nerve itself. The optic nerve travels through a collagenous sieve in the plane of the posterior sclera, the lamina cribrosa. The choroid is that portion of the uveal tract posterior to the retina. This layer is composed of various calibers of blood vessels that ultimately supply blood for the choriocapillaris. There are no lymphatic channels in the choroid.

The sclera is composed of dense, relatively disorganized collagen. It is opaque because of the nonhomogeneous structure of the collagen and the degree of hydration relative to the cornea. There are multiple scleral ostia for arteries, veins, and nerves, both posteriorly and anteriorly.

The orbit is composed of bones of the facial skeleton. Sutures between major bones exist in the superior nasal and superior temporal quadrants. Multiple vessels and nerves extend through the thin ethmoid bone from nasal sinus tissue medially. The orbital floor is poorly supported over the maxillary sinus and may rupture with increased intraorbital pressure. The nasolacrimal duct travels through a portion of the lacrimal bone. The optic nerve is protected by portions of the sphenoid bone. Major cranial nerves travel through the adjacent superior orbital fissure, also a portion of the sphenoid bone. There is no normal lymphoid tissue in the orbit outside of the lacrimal gland. The rectus muscle may be enlarged by inflammation in thyroid eye

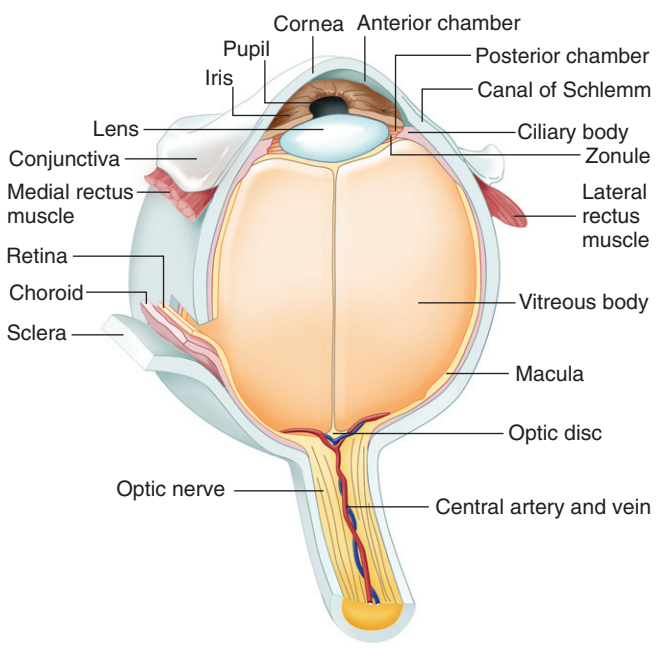

FIGURE 431-1. Anatomy of the eye.

disease, but the tendinous insertion into the sclera is not inflamed early in the course of the disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients may present with complaints of diminished vision, eye pain, red eyes, or pain around the eye. The causes may be primarily ophthalmic (e.g., cataract) or systemic (e.g., diabetic retinopathy). A comprehensive ophthalmologic examination also should evaluate for possible asymptomatic local (e.g., choroidal melanoma) or systemic (e.g., hypertensive retinopathy) abnormalities in patients with normal acuity and no subjective complaints.

Functional Evaluation

The most objective and common measure of ocular function is line letter acuity, with normal vision (Table 431-1) defined as the ability to see at 20 feet what a normal person sees at 20 feet (Fig. 431-2). Less than 20/20 vision can be caused by an abnormality anywhere from the tear film to the visual cortex of the occipital lobe (see Fig. 431-1). However, normal vision also includes other functions, such as the perception of color, motion, contrast, brightness, field, and depth, for which there is greater variation among individuals and no universally adopted, standardized scales. Normal visual acuity is potentially achievable in essentially all individuals, either naturally or with visual correction.

Correction of vision is based on the refraction of light (Fig. 431-3). The diopter (D) is the unit of measurement of the ability of an optical system to refract (bend) light. The normal human eye has the refractive capacity of approximately 60 D. If the eye is too short, light will be focused behind the eye (hyperopia). If the eye is too long, light will be focused in the vitreous in front the retina (myopia). Normally, a person can voluntarily control the crystalline lens, alternating between near and distant tasks. At approximately age 45 years, the lens becomes stiff, and the eye becomes set for distance (presbyopia). Refraction is the method of determining the amount of optical correction (strength of glasses) needed to establish 20/20 (6/6) vision.

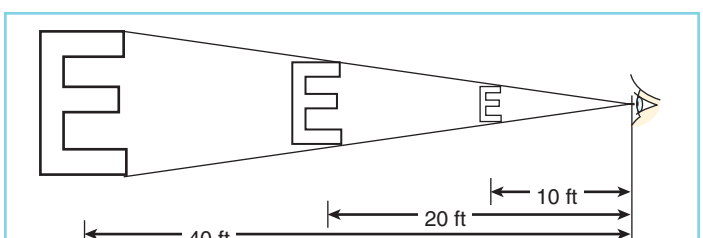

FIGURE 431-2. Snellen visual acuity. The most common test for visual acuity describes the eye's ability to resolve linear images at a test distance of 20 feet, approximating infinity (parallel rays of light). A 20/20 E subtends 5 minutes of arc at a distance of 20 feet, with each segment of the E subtending 1 minute of arc. The larger letters (e.g., 20/30, 20/40) are determined by the distance at which they subtend an angle of 5 minutes. Thus, an E that subtends 5 minutes at 40 feet, if viewed clearly at 20 feet, indicates 20/40 visual acuity.

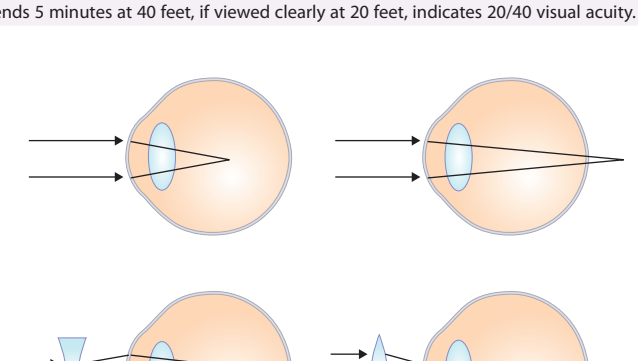

FIGURE 431-3. Myopia/hyperopia. A, In the myopic eye, parallel rays of light are focused anterior to the retina. A divergent lens can be used to compensate for the mismatch between refracting power and axial length. **B,** The hyperopic eye requires the additional power of a convergent lens to bring images into focus on the retina.

Examination of pupillary response assesses whether neural function is intact (see Figs. 432-2 and 432-4 in Chapter 432). Confrontational visual field testing (see Fig. 432-1 in Chapter 432) should be performed in each eye to detect gross quadrantic defects. Extraocular motility should be assessed to exclude nerve or muscle abnormalities (see Table 432-4 in Chapter 432). Color vision testing plates are a sensitive indicator of optic nerve function.

Diagnostic testing during a routine eye examination also includes external examination of the lids and adnexa, applanation tonometry to determine intraocular pressure, biomicroscopy (slit lamp examination) of the anterior segment, and ophthalmoscopic examination of the ocular fundus. Other office tests when indicated include exophthalmometry (measurement of proptosis), visual field and electrophysiologic testing, and vascular imaging (fluorescein angiography, mainly in diabetic patients; ocular computed tomography [OCT] to investigate retinal macular disease; and corneal topography).

The conjunctiva, cornea, lens, and anterior chamber are evaluated using a slit lamp. The slit lamp is composed of a binocular microscope with variable magnification (40× and 80×) in conjunction with adjustable light sources. An increased concentration of protein can be detected in the anterior chamber because of the Tyndall (flare) effect, indicating vascular incompetence associated with either inflammation or ischemia. Even individual inflammatory cells can be resolved with the slit lamp. A cobalt blue filter can be used to detect fluorescein dye that accumulates in regions of abnormal epithelium (dendrite of herpes simplex keratitis or a corneal abrasion). The slit beam is used to examine the crystalline lens to determine the degree of opacification from a cataract. By using a green filter with the 90 D lens, the retinal vessels and retinal vascular abnormalities such as microaneurysm can be seen at relatively high magnification.

COMMON CLINICAL CONDITIONS

Chronic Abnormal Vision

MYOPIA

Nearsightedness (myopia; see Fig. 431-3) is usually discovered during childhood when children cannot perform distant tasks during school (reading the

blackboard) or during school screening. Myopia usually progresses until the eye is fully developed, typically by age 20 to 25 years. Rapidly progressing myopia during childhood or at any time after age 25 years requires evaluation for juvenile glaucoma, diabetes mellitus (reversible metabolic changes in the crystalline lens), trauma (development of a cataract), or use of corticosteroids (development of a cataract). Myopia is usually fully correctable with glasses. Laser in situ keratomileusis (LASIK) is a surgical procedure that may be used in adults to correct myopia and other refractive errors, with 95% of patients achieving visual acuity of 20/40 or better. Complications of LASIK include glare symptoms, dry eye, and undercorrection or overcorrection. Rare but serious complications include epithelial ingrowth, diffuse keratitis, and flap dislocation.

Pathologic myopia is a heritable condition causing progressive weakening of the posterior sclera and resulting increases in the axial length of the eye. The posterior radius of curvature of the eye increases (posterior staphyloma). The refractive error is usually above −8.00 D and may be as high as −20.00 D in severe cases. Abnormal physical forces in pathologic myopia may lead to retinal hole formation, retinal detachment, or intraocular hemorrhage. Associated systemic conditions include trisomy 21, Cornelia de Lange's syndrome, Stickler's syndrome, and Marfan syndrome. Clinical surveillance must be maintained to watch for treatable complications such as retinal detachment. Pathologic myopia is usually treated with spectacles or contact lenses. Refractive procedures are less successful in pathologic myopia because of the severity of the refractive errors and the presence of posterior segment abnormalities. Surgical and laser procedures may be required to treat retinal and choroidal lesions (e.g., subretinal neovascularization).

HYPEROPIA

In hyperopia (farsightedness; see Fig. 431-3), in contrast to myopia, the eye tends to have a shorter than average axial length. Compensatory mechanisms of the crystalline lens may functionally correct small degrees of hyperopia until age 40 years, when the crystalline lens loses its pliability. The 40-year-old hyperopic changes from latent to manifest hyperopia simultaneously. The initial pair of glasses may have to correct for both distance and near tasks (bifocals). LASIK can correct up to 5 D of hyperopia.

ASTIGMATISM

Astigmatism usually is the result of irregularities in the radius of curvature of the cornea. Astigmatism is not a pathologic state, but rather a variation in anatomy; most people have some degree of astigmatism. Trauma to the cornea can cause alteration of structure, leading to irregular astigmatism. Symptoms are predominantly blurry vision and difficulty seeing fine detail. Regular astigmatism can be corrected with spectacle lenses or with rigid contact lenses, whereas irregular astigmatism requires rigid contact lenses. Some forms of astigmatism can also be corrected with laser ablation of the cornea.

KERATOCONUS

Keratoconus is an acquired irregularity of corneal curvature, possibly caused when inappropriate activation of matrix metalloproteinase weakens the structure of the cornea, particularly in the inferior nasal quadrant. Onset generally is during adolescence, and the process often evolves over 5 years or so. The prevalence in the United States appears to be about 55 cases per 100,000 people but is probably greater when subclinical cases diagnosed by computerized videokeratography are considered.

Patients typically have astigmatism, which may be severe. The condition is usually bilateral but not symmetrical. Mild degrees of keratoconus can be corrected with glasses or contact lenses. For severe cases, corneal transplantation (graft) often is very successful.

STRABISMUS

The control of simultaneous orientation of the two eyes to ensure that the visual axes of both eyes are aligned is not complete until several years following birth. Misalignments of the two eyes (strabismus) may be the result of abnormalities in the central nuclei of the brain, malfunction of one or several peripheral nerves, or intrinsic abnormalities of the rectus or oblique muscles (see Fig. 432-6 in Chapter 432). If the eyes are not simultaneously stimulated with the images of the same degree of clarity or complexity, only one eye will develop normally. The image processing ability of the blurred eye will not develop (amblyopia). Generally, amblyopia can be corrected until about age 7 to 8 years of age, after which an amblyopic eye is not likely to develop normal (20/20) vision. In most cases, only the central vision is affected. The peripheral vision in both eyes is likely to be equal and normal.

Amblyopia also may be caused by a marked difference in refractive error between the two eyes (anisometropic amblyopia) or eyelid ptosis (deprivational amblyopia). Ptosis may be neurogenic or mechanical (e.g., congenital eyelid hemangioma). To avoid amblyopia, it is extremely important to refer a child with strabismus to an ophthalmologist as soon as the strabismus is noted.

Esotropia is deviation of one or both eyes inward. Esotropia may not be clinically evident until the child is 3 to 4 months of age. Delay in facial maturation (underdeveloped nasal bridge) may give the appearance of esotropia, even though the visual axes are correctly aligned. In true strabismus, the light reflex will be in the center of one cornea and decentered in the other.

Exotropia is deviation of one or both eyes outward. Exotropia tends to be intermittent and less likely to result in amblyopia.

Both esotropia and exotropia may be treated by using appropriate corrections of refractive error with glasses (occasionally bifocals). Occasionally extraocular muscle surgery is necessary to correct alignment. To allow the second eye to develop to its full potential, amblyopia is corrected by occluding the stronger eye with a patch or by pharmacologically occluding (blurring) the better eye with atropine. Success is directly related to compliance.

DIPLOPIA (DOUBLE VISION)

Acute onset of diplopia is an ominous sign suggestive of a third nerve palsy (Chapter 432). Diplopia of any kind is an intolerable symptom, but vertical diplopia is less tolerated than horizontal diplopia.

COLOR VISION CHANGE

Most cases of congenital color blindness go undetected for many years. Acquired color deficiency at any age may be caused by a cataract or optic nerve disease.

CHANGE IN VISION

If only one eye has a change in vision, the problem, such as a cataract or retinal detachment, is most likely in that eye. If both eyes have a change in vision, the problem generally is outside of the eye, such as homonymous hemianopia (Chapter 432). Improvement of near vision in middle age may be a sign of cataract ("second sight") or hyperglycemia. Transient complete unilateral or bilateral loss of vision may be caused by vascular abnormalities inside or outside of the eye (Table 431-2).

Acute Eye Abnormalities

PAIN

The most severe eye pain (Table 431-3), typically associated with a red eye, is caused by acute angle-closure glaucoma. Sharp, intermittent pain is usually caused by ocular surface abnormalities (e.g., corneal foreign body). Burning pain that clears with blinking generally relates to tear-film abnormalities (dry eyes). Deep boring pain most often is associated with an ocular abnormality (e.g., uveitis).

RED EYE

A red or inflamed eye can be caused by conjunctivitis, iritis (anterior uveitis), acute glaucoma, corneal trauma, or infection (Table 431-4). Of these causes, all are typically painful, with the occasional exception of conjunctivitis.

TABLE 431-2 DIFFERENTIAL DIAGNOSIS OF SUDDEN VISUAL LOSS

UNILATERAL	BILATERAL
Amaurosis fugax (carotid artery stenosis)	Eclampsia
Central retinal artery occlusion	Vertebrobasilar infarct
Occipital lobe infarct	Trauma
Temporal arteritis	
Nonarteritic anterior ischemic optic neuropathy	
Hemorrhage	
Preretinal (high altitude, Valsalva)	
Vitreous	
Aqueous (hyphema)	
Trauma	

DISTORTED VISION

Distorted vision (metamorphopsia), which is the perception that straight lines are distorted or bowed, results from macular dysfunction. Causes include fluid under the retina, exudative macular degeneration, which tends to elevate the retina, and an epiretinal membrane, which tends to contract the retina.

NIGHT BLINDNESS

Retinitis pigmentosa, vitamin A deficiency, and systemic medications such as phenothiazines can cause true night blindness, in which patients have difficulty seeing any stars in the sky on a clear night and may be unable to ambulate without assistance in a dark environment. Patients with cataracts may have difficulty driving at night because of excessive glare and visual distortion.

SENSATION OF FLASHING LIGHTS

The sudden onset of flashes in the peripheral visual field suggests a posterior vitreous detachment with resulting traction of the vitreous on the peripheral retina, sometimes with a resulting retinal tear. The flashes, which may be more pronounced in the dark and with rapid eye movement, may be associated with the sudden onset of floaters, which can indicate debris or blood in the vitreous cavity. Because a tear in the retina can lead to a retinal detachment, urgent consultation with an ophthalmologist is required.

Flashing light with a migraine (Chapter 405) is described as scintillations or zigzagging lights that march across the visual field for a few minutes or as long as 30 minutes, sometimes associated with transient visual field loss. Headache is not universal.

FLOATERS

Floaters, which are caused by small aggregates in the vitreous cavity, result from the normal aging of the vitreous. The acute onset of vitreous floaters may be associated with uveitis or with the sudden onset of bleeding in the vitreous cavity owing to diabetes or sickle cell anemia. Acute floaters, however, particularly if associated with flashing lights, may indicate a posterior vitreous detachment or a retinal tear with an impending retinal detachment. Urgent ophthalmic referral is essential.

PHOTOPHOBIA

Photophobia, particularly if associated with eye pain, redness, and decreased vision, is a symptom of uveitis or traumatic iritis. Photophobia is also typical of acute migraine and meningeal irritation. Prompt ophthalmologic referral is prudent.

HALOS AROUND LIGHTS

Patients with cataracts commonly see halos around lights, particularly when driving at night. Episodic decreased vision, redness, and halos around lights may be symptoms of impending angle-closure glaucoma. Halos also can occur as a complication of LASIK eye surgery.

FOREIGN BODY SENSATION

A foreign body sensation is commonly caused by dry eyes. An entropion (Fig. 431-4) or misdirected lashes (trichiasis) also can cause a foreign body sensation. Most corneal abrasions cause severe pain, but minor corneal abrasions may be associated with a foreign body sensation rather than the severe pain that usually accompanies a more severe abrasion. An arc welder burn causes a punctate corneal keratopathy, and foreign body sensation may be a prominent symptom. A true conjunctival or corneal foreign body also may be present.

EXCESSIVE TEARING

Impairment of tear drainage can occur with an ectropion or any obstructions of the nasolacrimal drainage system. An entropion or abnormal lashes rubbing on the cornea (trichiasis) stimulate tear production.

EYELID TWITCHING

Any irritation of the conjunctiva or cornea can cause the eyelids to twitch. Occasional twitching of the lids usually is associated with stress or adrenergic stimulation. Benign essential blepharospasm is severe spasm of the lids leading to functional impairment. Multiple sclerosis (Chapter 419) also can cause lid spasm.

CONJUNCTIVITIS

Any ocular inflammation, including corneal ulcers, angle-closure glaucoma, endophthalmitis, and uveitis can be associated with secondary conjunctivitis. Conjunctivitis usually involves the entire conjunctiva, is associated with a discharge, and usually is not associated with pain (see Table 431-4).

PTOSIS (DROOPY EYELID)

Ptosis (Fig. 431-5) can be caused by a third nerve palsy, which usually is associated with diplopia and a reduction in elevation, depression, and medial movement of the pupil. Horner's syndrome (see Fig. 432-5 in Chapter 432) is associated with a small pupil. With myasthenia gravis (Chapter 430), other typical features of muscle weakness are usually present or can be elicited. Some patients have mild senile ptosis, especially after eye surgery.

TABLE 431-3 CAUSES OF EYE PAIN

Blepharitis	Glaucoma
Blocked tear duct	Hordeolum (stye)
Chalazion	Iritis

TABLE 431-4 DIFFERENTIAL DIAGNOSIS OF COMMON CAUSES OF INFLAMED EYE*

FEATURE	ACUTE CONJUNCTIVITIS	ACUTE IRITIS†	ACUTE GLAUCOMA‡	CORNEAL TRAUMA OR INFECTION
Incidence	Extremely common	Common	Uncommon	Common
Discharge	Moderate to copious	None	None	Watery or purulent
Vision	No effect on vision	Slightly blurred	Markedly blurred	Usually blurred
Pain	None	Moderate	Severe	Moderate to severe
Conjunctival injection	Diffuse: more toward fornices	Mainly circumcorneal	Mainly circumcorneal	Mainly circumcorneal
Cornea	Clear	Usually clear	Steamy	Change in clarity related to cause
Pupil size	Normal	Small	Moderately dilated and fixed	Normal or small
Pupillary light response	Normal	Poor	None	Normal
Intraocular pressure	Normal	Normal	Elevated	Normal
Smear	Causative organisms	No organisms	No organisms	Organisms found only in corneal ulcers related to infection

*Other less common causes of red eyes include endophthalmitis, foreign body, episcleritis, and scleritis.
†Acute anterior uveitis.
‡Angle-closure glaucoma.

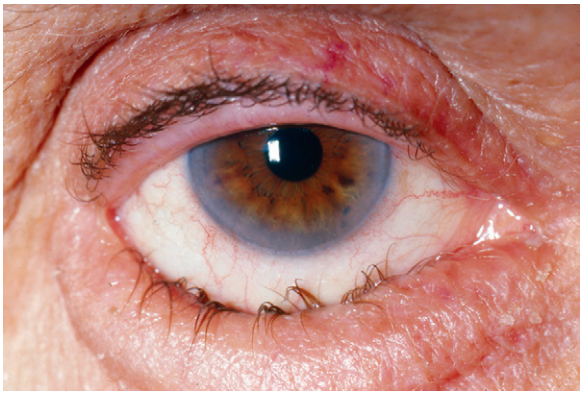

FIGURE 431-4. Involutional entropion. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology,* 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

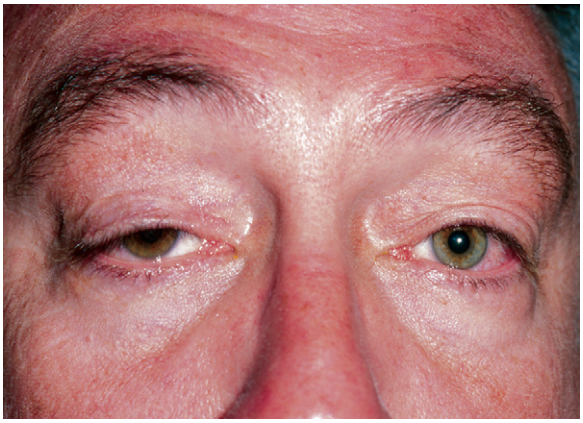

FIGURE 431-5. Ptosis of the right upper lid. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology,* 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

PROPTOSIS (EXOPHTHALMOS)

Proptosis, or a prominent globe, can be a manifestation of thyroid abnormalities, especially Graves' disease (Chapter 233), in which proptosis is subacute and bilateral but sometimes asymmetrical (Fig. 431-6). An orbital pseudotumor can cause acute, usually unilateral proptosis, with severe pain, particularly with eye movement, and often with decreased vision. An optic nerve tumor causes chronic, unilateral proptosis associated with a slow onset of visual field loss. Acute cellulitis can be associated with unilateral proptosis, severe redness, and moderate to severe pain, commonly with sinusitis and an elevated white blood cell count.

SMALL PUPIL

A unilateral small pupil is best detected in dark conditions. Causes include Horner's syndrome, associated with ptosis on the same side; the bilaterally small, poorly reacting pupils of tertiary syphilis (Argyll Robertson pupils), which accommodate with normal constriction to a near object; miotic drops (e.g., pilocarpine); traumatic iritis; uveitis; and recent eye surgery.

LARGE PUPIL

Any α-adrenergic or anticholinergic agent placed into the eye can cause a large pupil. With eye trauma, the iris sphincter muscle can be damaged, and an abnormally large pupil can result. Tears in the iris sphincter can sometimes be appreciated on slit lamp examination. Third nerve palsy may cause a dilated pupil associated with ptosis and decreased elevation, depression, and medial eye movement. Adie's pupil (see Fig. 432-3 in Chapter 432) is an idiopathic, unilateral large pupil that is hypersensitive to weak cholinergic stimulation. Recent eye surgery, uveitis, closed-angle glaucoma, and traumatic iritis can cause a large pupil.

LEUKOKORIA

Leukokoria (white pupil) in a child is often a sign of retinoblastoma. However, any condition that changes transmission of ambient light to reflection of ambient light through the pupil may cause this sign. Some of the more common nonretinoblastoma conditions presenting with leukokoria (Table 431-5) include cataracts, retinal detachment, persistent hyperplastic primary vitreous (a developmental anomaly of the vitreous resulting in intraocular fibrosis and retinal detachment), Coats' disease (a developmental vascular malformation of the retina leading to retinal detachment), and ocular toxocariasis (a parasitic intraocular nematode infection, which leads to intraocular scarring and retinal detachment).

Familial exudative vitreoretinopathy (FEVR)

Eyelid Abnormalities

ECTROPION AND ENTROPION

An ectropion is an out-turning of the lower lid (Fig. 431-7), typically with the inner part of the lower end visible between the eye globe and the lid. Causes include aging, scarring, a mass on the lower lid, and seventh nerve palsy. Common symptoms include burning, itching, tearing, and the sense of a foreign body. Treatment is symptomatic, unless the underlying cause can be surgically corrected.

FIGURE 431-8. Bilateral chalazion in the upper eyelids.

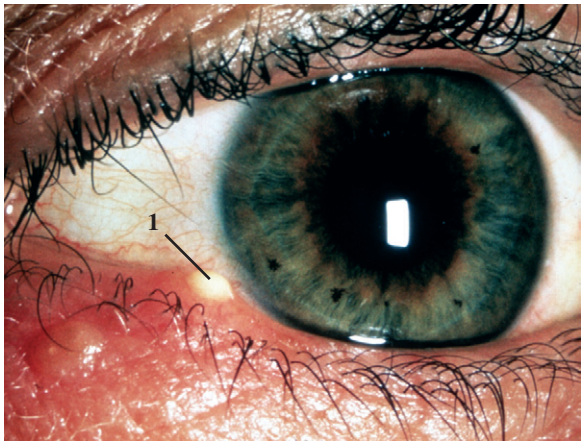

FIGURE 431-9. A lower lid stye *(1)*. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology,* 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

An entropion, which is an in-turning of the lower lid (see Fig. 431-4), is usually age-related and associated with irritation, burning, and a foreign body sensation. If it leads to trichiasis, in which the eyelashes rub or abrade the cornea, the lashes can be removed with forceps or surgery.

CHALAZION

A chalazion (Fig. 431-8) is a localized lipogranulomatous inflammation that results when the eyelid reacts to the contents of a ruptured sebaceous (meibomian) gland. The retained, lipid-rich sebaceous material acts as a foreign material that stimulates a lipogranulomatous foreign body inflammatory reaction. A painless or slightly tender, poorly demarcated, nonmobile nodule forms under the eyelid skin. Most lesions resolve over days to weeks with warm compresses or without specific treatment. Occasionally, an ophthalmologist may inject steroids to reduce inflammation or debulk the foreign material by incision and drainage through the tarsal conjunctiva. Some individuals may have recurrent chalazion.

HORDEOLUM (STYE)

A hordeolum (stye) (Fig. 431-9) is an extremely painful abscess in a hair or eyelash follicle or in a sebaceous gland. Styes are usually self-limited infections that respond to warm compresses and topical antibiotics (e.g., bacitracin or erythromycin ointment or moxifloxacin or gatifloxacin drops). Incision and drainage may be performed by an ophthalmologist if symptoms do not improve within 48 hours.

BLEPHARITIS

Blepharitis (Fig. 431-10), which is a nonspecific inflammation of the eyelid skin, is common, particularly in men. The condition is usually bilateral and symmetrical. Rosacea (Chapter 447) is the most common associated cutaneous condition, and *Staphylococcus aureus* is the most common infectious agent. If untreated, blepharitis becomes chronic and may lead to corneal and

FIGURE 431-10. Staphylococcal blepharitis. The lid margins are very red and under high magnification demonstrate tiny ulcerations. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology,* 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

conjunctival inflammation (blepharoconjunctivitis). Ophthalmic antibiotic ointment (e.g., bacitracin or erythromycin) is more efficacious than eye drops, but systemic antibiotics (e.g., minocycline, 50 to 100 mg, or doxycycline, 100 mg, once daily; tetracycline, 250 mg twice daily; or erythromycin, 250 mg three times daily) are recommended if there is any evidence of inflammation of the cornea or conjunctiva.

In seborrheic blepharitis, exfoliated keratinous debris accumulates along the eyelid margin, particularly at the follicles of the eyelashes, and irritates the conjunctiva. Treatment of this chronic condition is directed at mechanically removing the keratinous debris by scrubbing the eyelid and eyelashes daily with a mild detergent ("baby shampoo") in warm water applied with a soft cloth.

BENIGN EYELID NEOPLASMS

Skin tags, also known as squamous papillomas, are the most common benign skin lesions. Other skin lesions include seborrheic keratitis, actinic keratitis, inverted follicular keratitis, and benign lesions of the eccrine and apocrine systems. Most of these benign lesions are cured by simple excision.

SEBACEOUS GLAND CARCINOMA

Sebaceous gland carcinoma originates from sebaceous glands either in the tarsal plate (meibomian gland) or associated with eyelashes (glands of Zeis) and is capable of producing widespread metastasis resulting in death. Muir-Torre syndrome is sebaceous tumors associated with visceral malignancy. Except for chronic, unilateral blepharitis, owing to the peculiar manner of spread of this tumor in the plane of the skin epithelium (pagetoid spread) without causing the formation of nodules, few symptoms occur early in the course of the disease. The tumor may progress to involve the tarsal conjunctiva, the bulbar conjunctiva, and even the corneal epithelium. A characteristic sign is regional loss of eyelashes. When the mass thickens, it may have the appearance of a chalazion, and a history of multiple chalazia in the same region of the eyelid is suggestive of sebaceous gland carcinoma.

Treatment is surgical removal. Surgical margins are difficult to estimate because of the intraepithelial extension of the tumor. In advanced cases, removal of the eyelids, eye, and orbital contents (exenteration) may be necessary.

BASAL CELL CARCINOMA

Basal cell carcinoma (Fig. 431-11), which originates from the basal cell layer of the epithelium, is a common cutaneous malignancy (Chapter 210). The lesion, which usually is asymptomatic, is often a well-demarcated, elevated nodule that may have a central region of ulceration and fine cutaneous vascular channels (telangiectasias). A common benign cutaneous lesion, sometimes confused clinically with basal cell carcinoma, is seborrheic keratosis (Chapter 448), which tends to be soft and appear hyperpigmented; the most common site is the lower eyelid, especially in the nasal quadrant. Basal cell carcinoma, particularly near the medial canthus, may extend posteriorly into the soft tissues of the orbit. Imaging before surgical excision for medial canthal lesions may be necessary to determine the true extent of the tumor. Basal cell carcinoma is treated by surgical excision, using Mohs' technique with intraoperative histologic evaluation to determine adequate margins of excision, if possible.

Metastasis is extremely rare. Generally with early detection and adequate excision of the local lesion, the prognosis is excellent.

EYELID SQUAMOUS CELL CARCINOMA

Eyelid squamous cell carcinoma, which is much less common than basal cell carcinoma, arises from the surface squamous epithelium. Ultraviolet light exposure is the major risk factor. In contrast to basal cell carcinoma, squamous cell carcinoma can metastasize, most often to regional lymph nodes. Treatment is surgical excision. Except in rare circumstances, such as in immunosuppressed patients or patients with xeroderma pigmentosa, the prognosis is excellent.

Ocular Surface Abnormalities

DRY EYES

Even minor disturbances in the tear film can cause itching, burning, pulling, and transient changes in vision. Some patients are particularly disturbed by dry eyes that cause conjunctival hyperemia without purulent discharge. Paradoxically, decreased tearing can result in irritation and secondary increased (reflux) tearing.

Most daily tear production is not by the lacrimal gland but by small collections of lacrimal glands, mucous producing glands, and sebaceous glands located throughout the conjunctiva, eyelid, and anterior orbital soft tissue. Over time, particularly in women, production of tear film diminishes. Because tear film production is lower during sleep, patients often note symptoms on awakening followed by slow resolution over minutes or hours. Wind and low humidity environments, such as in commercial airliners, can exacerbate symptoms. The reduction in aqueous components of tears is often associated with a compensatory increase in mucous production, which tends to blur vision until the patient blinks or uses supplemental tears. These symptoms are particularly prominent in persons who have rheumatoid arthritis (Chapter 272), Sjögren's syndrome (Chapter 276), Stevens-Johnson syndrome (Chapter 448), and ocular cicatricial pemphigoid (Fig. 431-12).

Treatment is not definitive and is rarely satisfactory. No medication increases the production of tears. Low-viscosity artificial tears (e.g., polyethylene glycol 400 0.4%), which do not tend to blur vision but have a short duration of action, are best used during visually important tasks. High-viscosity tears (e.g., carboxymethylcellulose sodium) have a longer duration of action but tend to blur vision; they are best used at bedtime to maintain lubrication of the ocular surface during sleep. When artificial tears do not control symptoms, occlusion of the nasolacrimal duct with synthetic plugs or permanent surgical occlusion tends to retain the tears that are produced. Anti-inflammatory drugs (e.g., cyclosporine 0.05% drops, every 12 hours indefinitely) can preserve glandular tissue that may be affected by local inflammation. For patients with systemic disease associated with dry eyes, effective treatment of the systemic disease sometimes improves the eye abnormalities.

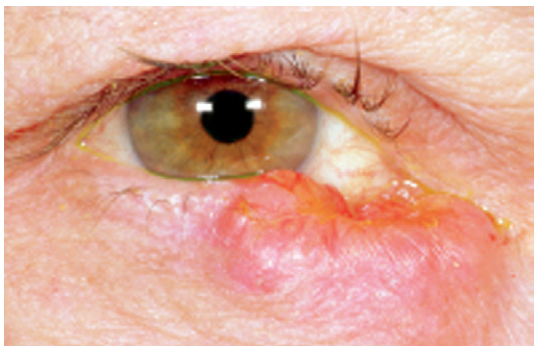

FIGURE 431-11. A typical nodular basal cell carcinoma. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology,* 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

PINGUECULA AND PTERYGIUM

A pinguecula (Fig. 431-13) consists of a limbal (at junction of cornea and sclera) and bulbar conjunctival degenerative process caused by ultraviolet light damage to the subepithelial tissue. It is very common and rarely causes symptoms. If the supportive tissue degeneration extends into the cornea, it becomes a pterygium (Fig. 431-14), which may cause visual changes and require surgical excision.

RECURRENT EROSION

Recurrent erosion of the cornea usually is a delayed reaction to minor traumatic corneal abrasion. The abrasion heals abnormally, resulting in a weakness of the epithelial attachment to underlying tissue. Weeks to months to years later, the patient is awakened in the middle of the night with extreme

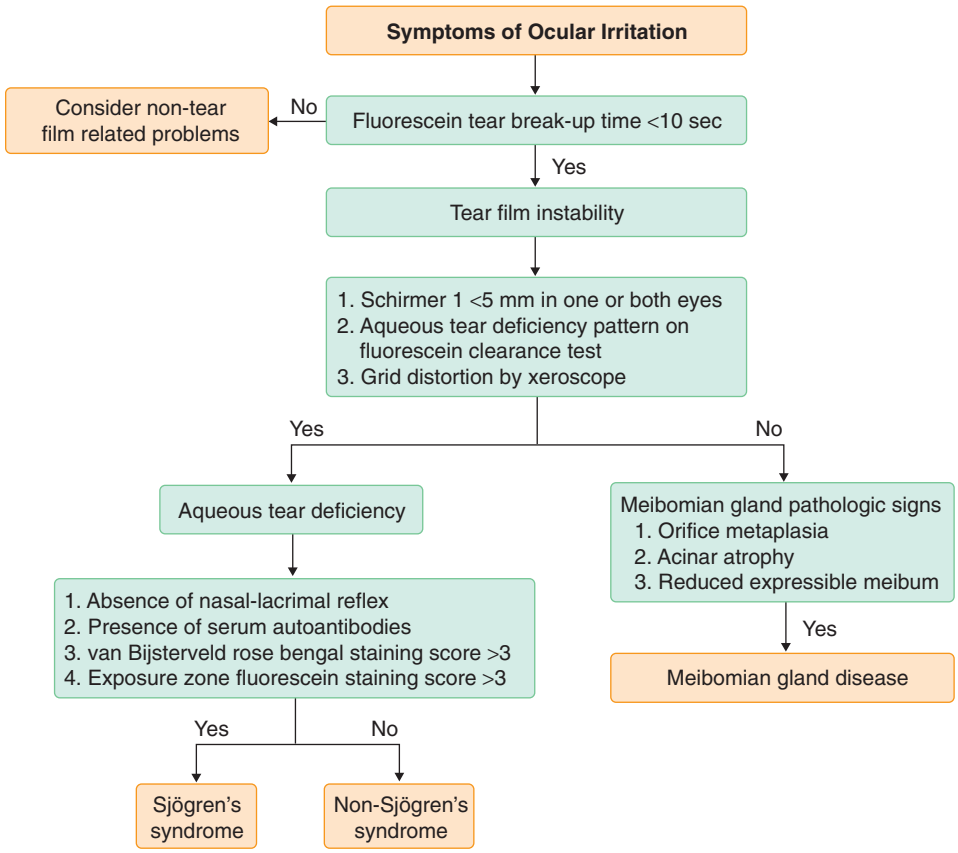

FIGURE 431-12. Diagnostic algorithm for ocular irritation. (Modified from Pflugfelder SC, Tseng SC, Sanabria O, et al. Evaluation of subjective assessments and objective diagnostic tests for diagnosing tear-film disorders known to cause ocular irritation. *Cornea.* 1998;17:38-56.)

FIGURE 431-13. Pinguecula. These lesions are found at the 3-o'clock and 9-o'clock positions and are extremely common, especially in older patients. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology,* 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

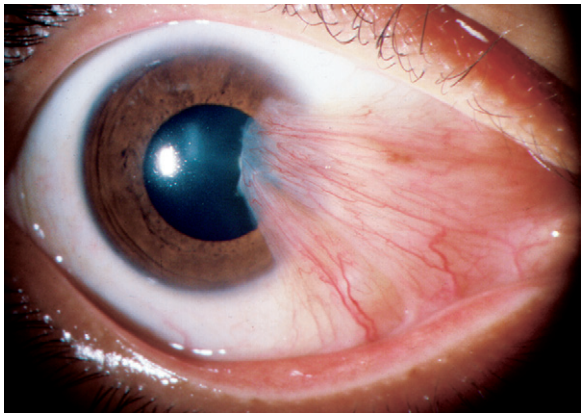

FIGURE 431-14. Pterygium. These lesions are found in the horizontal meridian, most common nasally. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology,* 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

ocular pain on opening the eyelids. The epithelium has become "stuck" to the overlying upper lid and is mechanically abraded. The condition is treated with hyperosmotic drops and ointment. There is a tendency to recurrence.

ACCIDENTAL TRAUMA

With ocular trauma, many tissues of the eye can be easily disrupted, and the effects of trauma may not be manifest for months or even years after the episode of trauma. If the traumatic episode disrupts the eye wall (cornea and sclera), surgical repair is necessary, usually urgently. If the eye wall is intact, surgical treatment is often not necessary, at least initially.

CORNEAL ABRASION

Corneal abrasion, one of the most common forms of ocular injury, may be caused by shearing trauma or hypoxia associated with overwearing of contact lenses. Symptoms are often intense and intolerable. Healing (i.e., re-epithelialization) of the cornea occurs within 24 to 48 hours. Rust from metallic fragments is toxic to the epithelium and should be removed. Fungal keratitis may complicate injuries from fingernails or vegetable matter, such as tree branches. Treatment usually consists of a topical antibiotic (e.g., erythromycin ointment, four times daily for 10 days) to prevent bacterial keratitis. Subsequent scarring usually does not occur unless deeper structures, such as Bowman's membrane, are affected. Topical anesthetics never should be prescribed to control pain because they increase the risk for microbial keratitis and scarring and may delay healing.

MAJOR OCULAR TRAUMA

Hyphema (Fig. 431-15) is hemorrhage into the anterior chamber caused by blunt trauma. If the patient is in an intensive care unit and supine, the blood will distribute uniformly over the iris to cause the appearance of increased pigmentation of the iris (heterochromia iridis). If the patient has been sitting,

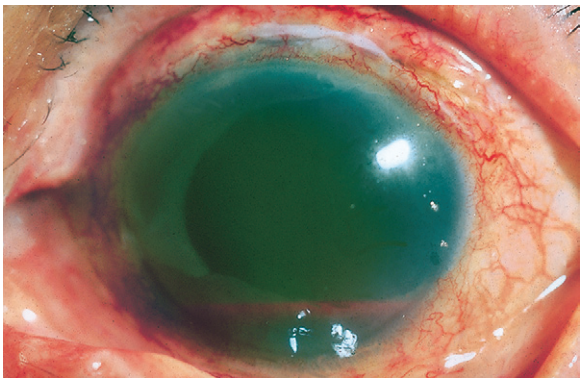

FIGURE 431-15. Hyphema following cataract surgery. (Courtesy of Dr. Myron Yanoff.)

the blood may settle by gravity to form an aqueous-blood interface with the blood in the dependent portion of the anterior chamber. Hyphema, which is a sign of serious ocular damage, may lead to secondary glaucoma and blood staining of the cornea. It requires prompt evaluation by an ophthalmologist.

The most common site of rupture of a globe is at the limbus (junction of cornea and sclera), where a pigmented mass may be noted. The mass may be either a blood clot or an anteriorly displaced uveal tract (usually iris). Any manipulation of the globe may force the remaining intraocular tissue through the wound and may make the injury irreparable. Surgical repair is usually indicated.

Cataract and retinal detachment are not common except in severe accidental trauma. A unilateral cataract or unilateral glaucoma may occur decades after the injury, even when an injury is too minor to be recalled. Traumatic cataract and traumatic glaucoma are treated in the same manner as other forms of these conditions.

INFLAMMATORY EYE DISORDERS

Uveitis

Inflammation of any part or parts of the uveal tract (iris, ciliary body, and choroid) may be called anterior or posterior uveitis, iritis, iridocyclitis, or choroiditis. Symptoms include a red eye (see Table 431-4), decreased vision, and photophobia. The inflammation is chronic, and a cause is rarely found. However, uveitis accompanies many autoimmune diseases, often without correlation with the activity of the systemic inflammation. Anterior uveitis or conjunctivitis is nearly universal in patients with reactive arthritis (Chapter 273). About 25% of patients with ankylosing spondylitis (Chapter 273) develop acute, recurrent anterior uveitis. Two to 12% of patients with inflammatory bowel disease (Chapter 143) develop anterior uveitis, which is also common with psoriatic arthritis but not with psoriasis alone (Chapters 273 and 446). Treatment with topical corticosteroids (e.g., prednisolone acetate 1%, one drop in the affected eye or eyes every 1 to 6 hours while awake) is usually sufficient to control the ocular disease.

Endophthalmitis

Endophthalmitis is extensive inflammation within the eye from any cause. Most cases of endophthalmitis involve a breach in the eye wall (cornea and sclera), associated with either accidental trauma (incidence of approximately 5%) or surgical procedures (incidence of approximately <0.1%). The initial symptom is usually decreased vision followed by dull ocular pain. The initial sign is often evidence of inflammatory cells either within the aqueous (anterior uveitis) or within the vitreous (vitreitis). The cells can be seen only by slit lamp biomicroscopy. Common microbial organisms include toxin-producing gram-positive species and gram-negative species that are often associated with rapidly destructive course. Other organism of relatively low virulence, *Propionibacterium acnes* and *Staphylococcus epidermidis,* follow a more indolent course with less potential destruction. Metastatic endophthalmitis infection from a primary source outside of the eye is an unusual cause.

Diagnosis is established by sampling anterior chamber fluid or preferably vitreous fluid (vitreous tap) and evaluation of that fluid by Gram stain and culture. Treatment often requires outpatient intravitreal injection of antibiotics. In severe cases, the microbial and inflammatory debris burden is reduced by performing a vitrectomy through a pars plana incision. Under certain

TABLE 431-6 OPHTHALMIC DISORDERS ASSOCIATED WITH CONJUNCTIVITIS

DISORDER	ACUTE OR CHRONIC	UNILATERAL OR BILATERAL	KEY SYMPTOMS	DEGREE OF INJECTION	DISCHARGE TYPE	OTHER FEATURES
Viral conjunctivitis	Acute	Bilateral, possibly asymmetrical	Itching, burning, soreness	4+	Watery	Preauricular lymphadenopathy
Bacterial conjunctivitis	Acute	Unilateral or bilateral	Burning	3+	Heavy, mucopurulent	Lids possibly adherent
Chlamydial conjunctivitis	Subacute, chronic	Usually unilateral	Burning, irritation	2+	Scant, mucopurulent	Usual occurrence in young, sexually active adults
Herpes simplex conjunctivitis	Acute	Unilateral	Photophobia, irritation	1-2+	None	Dendritic ulcer on the cornea or vesicles on the lid possible
Allergic conjunctivitis	Chronic	Bilateral	Itching	2+	Stringy, mucoid	Usual occurrence in atopic persons, possible seasonal symptoms
Blepharitis	Chronic	Bilateral	Itching, burning, foreign body sensation	1-2+	Usually none	Inflammation and crusting of lid margins
Dry eye	Chronic	Bilateral	Foreign body sensation	1+	Mucoid in severe cases	Punctate fluorescein staining of the cornea

FIGURE 431-16. Eyelid abscess. Preseptal cellulitis, commonly resulting from minor penetrating trauma, may evolve into an abscess. Treatment requires incision and drainage followed by systemic antibiotics.

circumstances, corticosteroids and antibiotics are injected simultaneously to minimize the irreversible destructive effects of inflammation to the retina.

Allergic Conjunctivitis

Allergic conjunctivitis (Table 431-6) is commonly associated with atopy, hay fever, and allergic rhinitis (Chapter 259). Itching, a foreign body sensation, and a watery discharge are common. Treatment includes cool compresses and topical vasoconstrictors or antihistamines (e.g., naphazoline drops, four times daily during the allergic season, or levocabastine drops, four times daily). Long-term treatment with mast cell stabilizers (e.g., pemirolast drops, four times daily during the allergic season) or the combination of an antihistamine plus a mast cell stabilizer (e.g., olopatadine drops, two times daily during the allergic season) can be extremely effective in treating chronic symptoms.

INFECTIOUS EYE DISORDERS

Cellulitis

Preseptal cellulitis (Fig. 431-16) is soft tissue inflammation of the eyelid anterior to the orbital septum. The orbital septum divides the soft tissues of the eyelid from the soft tissues of the orbit. Orbital tissue is more susceptible to damage by the inflammation than is the preseptal tissue.

The clinical signs of preseptal cellulitis include soft tissue swelling, hyperemia, and conjunctival chemosis (edema). Movement of the eye is not restricted. Extension of inflammation posterior to the orbital septum is indicated by proptosis of the globe and ophthalmoplegia (restricted motion). Treatment of preseptal cellulitis includes oral antibiotics (e.g., amoxicillin-clavulanate, 500 mg orally every 8 hours for 10 days). Treatment of orbital cellulitis, which can lead to septic optic neuritis, intracranial spread, and cavernous sinus thrombosis, may require intravenous antibiotics and surgical drainage of a paraorbital abscess.

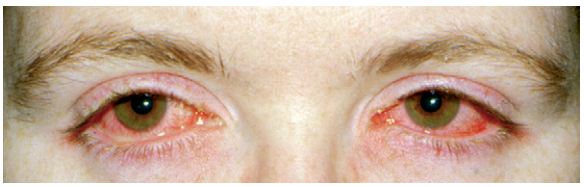

FIGURE 431-17. Diffuse injection of the conjunctiva with a watery discharge is evident in this case of viral conjunctivitis. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology,* 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

Adenoviral Conjunctivitis

Viral conjunctivitis (Fig. 431-17) is common (see Table 431-6), and adenoviral conjunctivitis (especially subtypes 7, 11, and 18) is the most common type. The condition is highly contagious through direct contact or inhalation of respiratory particles. After an incubation period of 5 to 15 days, the patient presents with very red eyes (see Table 431-4), itching, burning, a foreign body sensation, and often a discharge and ocular discomfort (see Table 431-3), which persist for 5 to 15 days. Preauricular lymphadenopathy may be present, and a history of upper respiratory tract infection is common. The disease is self-limited, and treatment is aimed at patients' comfort. Cool compresses are often soothing. Patients are advised to wash their hands frequently. Topical antibiotics are not required, and topical corticosteroids are contraindicated.

Bacterial Conjunctivitis

Fewer than 5% of cases of conjunctivitis are caused by bacteria, mostly *Staphylococcus, Haemophilus,* or *Streptococcus* species. Patients have a mucoid or purulent discharge (Fig. 431-18), often with crusting and edema of the conjunctiva (chemosis) and lids. Bacterial conjunctivitis responds to broad-spectrum antibiotic solutions or ointments (e.g., topical erythromycin ointment three times daily for 2 weeks) (Table 431-7).

Chlamydial Conjunctivitis

Adult inclusion conjunctivitis is a chronic conjunctivitis caused by sexual transmission of *Chlamydia trachomatis* (Chapter 326). Patients often have preauricular lymphadenopathy. Oral erythromycin (500 mg orally, four times daily for 7 days) or azithromycin (1 g orally twice daily for 7 days) is required. Trachoma, which is a chronic cicatricial conjunctivitis after repeated chlamydial infection (Chapter 326), is the world's leading cause of corneal blindness. It causes an entropion, inversion of the eyelashes (trichiasis), corneal vascularization, and opacification. Topical erythromycin or tetracycline, twice daily for 3 to 4 weeks, can be effective, but surgical epilation or eyelid reconstruction may be required.

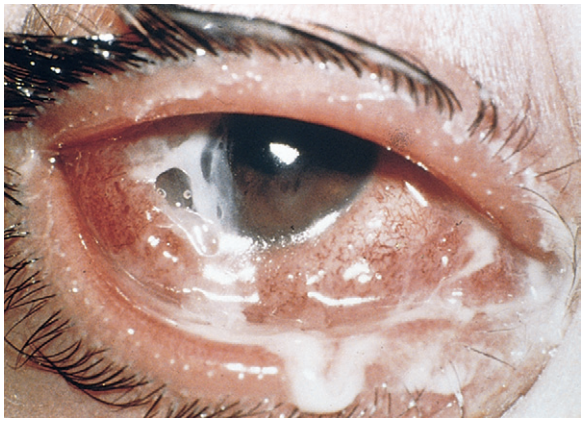

FIGURE 431-18. Bacterial conjunctivitis. Purulent discharge and conjunctival hyperemia suggest bacterial conjunctivitis. Viral conjunctivitis produces watery discharge, foreign body sensation, preauricular lymphadenopathy, and conjunctival follicles seen on slit lamp examination. TABLE 431-7 TOPICAL ANTIBIOTICS FOR EYE INFECTIONS

DRUG	TYPE	CONCENTRATION	DOSE
Moxifloxacin	Drops	0.5%	1 drop 4 times daily
Gatifloxacin	Drops	0.5%	1 drop 4 times daily
Ciprofloxacin	Drops	0.3%	1 drop 4 times daily
Gentamicin	Drops	0.3%	1 drop 4 times daily
Ofloxacin	Drops	0.3%	1 drop 4 times daily
Bacitracin	Ointment	500 U/g	Put in eye 4 times daily
Tobramycin	Ointment	0.3%	Put in eye 4 times daily
Erythromycin	Ointment	0.5%	Put in eye 4 times daily

Herpes Simplex Keratitis

Herpes simplex keratitis is the most common cause of central corneal ulcer (Fig. 431-19). Herpes simplex virus also can cause vesicular eyelid dermatitis. Initially, the main signs of primary herpes simplex keratitis are a red eye and a corneal epithelial dendritic ulcer. With appropriate antiviral therapy (e.g., trifluridine drops every 2 hours for 1 to 2 weeks), the keratitis usually heals without scarring. Recurrent herpes simplex keratitis may be precipitated by fever, menses, sunlight, irradiation, or stress. With recurrence, the disease may extend into the corneal stroma and cause a red eye, ocular discomfort, blurred vision, and corneal scarring. The treatment of stromal involvement is multifactorial and may not be successful. Corneal transplantation may be needed.

Herpes Zoster Ophthalmicus

Herpes zoster ophthalmicus (shingles, Chapter 383) has a propensity to involve one or more branches of the trigeminal nerve. The virus also can affect the uveal tract and, in immunosuppressed patients, the retina (i.e., acute retinal necrosis). When the trigeminal nerve is involved, spread to the inside of the eye (uveitis) is most likely if vesicles are present in the inner corner of the eyelids or on the nose, especially the tip of the nose. If the uvea is not involved, the skin lesions heal with some scarring but no long-term effects. In patients with moderate to severe skin involvement, treatment can be started with oral acyclovir (800 mg orally five times per day for 7 to 10 days). If uveitis develops, the treatment (e.g., prednisolone acetate drops 1% four times daily and scopolamine drops 0.25% three times daily) can be extended and difficult.

Pseudomonal and Gonococcal Keratitis

Keratitis, which is inflammation of the corneal stroma, can be caused by spread of pathogens internally from a corneal ulcer. *Pseudomonas aeruginosa* (Chapter 314), which causes a particularly virulent keratitis, is the most common gram-negative pathogen and is especially common in wearers of contact lenses. To avoid internal spread, urgent treatment is necessary (e.g., fortified tobramycin or gentamicin, 1.5 mg/mL every hour, alternating with fortified cefazolin, 50 mg/mL every hour, so a treatment is given each one-half hour around the clock). The dosage and duration of the treatment depend on the response.

Another gram-negative cause of a virulent keratitis is *Neisseria gonorrhoeae* (Chapter 306). Corneal infection is accompanied by copious weeping and a characteristic hyperpurulent discharge. Prompt treatment is essential in preventing corneal perforation.

Cytomegalovirus Retinitis

Cytomegalovirus retinitis (Chapter 384) is unusual except in immunosuppressed patients, especially patients with human immunodeficiency virus infection. Clinically, a central retinochoroiditis is seen. The presumptive diagnosis is made on the characteristic intense, retinal, wedge-shaped reaction, with considerable exudates and hemorrhages, giving the terms "pizza pie retinitis" and "hemorrhagic cottage cheese retinitis" to the entity. Treatment is antiviral drugs: ganciclovir (5 mg/kg intravenously twice daily, two to three times per week), foscarnet (90 mg/kg intravenously twice daily, twice per week), or cidofovir (5 mg/kg intravenously, weekly for 3 weeks) with follow-up maintenance.

Acanthamoeba Keratitis

Acanthamoeba species (Chapter 360) can cause a severe, blinding keratitis. Contact lens wearing is a major risk factor. A characteristic stromal ring infiltrate develops, and uveitis may occur. Using a confocal microscope, the acanthamebic parasite can be observed clinically as a pear-shaped cyst (11 to 15 μm). Numerous treatment protocols exist (e.g., polyhexamethyl biguanide 0.02% drops every hour). The duration and dose depend on the response, but the ideal treatment is not yet in hand.

Toxoplasmic Retinitis

Toxoplasma gondii (Chapter 357) causes both a congenital and acquired retinochoroiditis, which is more common in immunosuppressed patients. The lesions begin as an acute retinitis that atrophies centrally and pigments peripherally as it heals. The protozoa are found both in free and encysted forms within the retina. The condition may be self-limited and diagnosed as a healed incidental finding that does not need treatment. When active lesions are in the macula or a severe vitreitis causes at least a two-line decrease in vision, 4 to 6 weeks of quadruple therapy (pyrimethamine, 200 mg oral loading dose then 25 mg orally daily; folinic acid, 10 mg orally every other day; sulfadiazine, 2 g oral loading dose then 1 g four times daily; and oral corticosteroids, e.g., prednisone, 20 to 60 mg orally daily beginning at least 24 hours after antibiotic therapy is started and tapered 10 days before stopping antibiotics) usually produces good results. Alternative regimens may include clindamycin (150 to 450 mg orally three to four times daily) or atovaquone (1 g oral loading dose then 500 mg daily).

Fungal Endophthalmitis

Endophthalmitis is a potentially disastrous infection of the inside of the eye, often leading to blindness. The main fungal causes are *Candida, Coccidioides,* and *Aspergillus* species, which can gain access inside the eye either by traumatic introduction or through hematogenous spread. The patient presents with a red eye, ocular pain, and decreased vision. Multiple vitreous abscesses tend to be caused by fungi, whereas a solitary abscess is more likely caused

by bacteria. Usually a vitreous "tap" (biopsy) is performed for culture and to guide to therapy.

Tuberculosis

About 1% of patients with pulmonary tuberculosis (Chapter 332) have uveal involvement, usually as iridocyclitis or diffuse choroiditis. Painless progressive visual loss is the most common symptom. Small yellow choroidal lesions may be seen, and retinal periphlebitis may occur secondarily. Treatment is as for the primary disease.

Syphilis

About 5% of patients with secondary syphilis (Chapter 327) develop anterior uveitis or neuroretinitis. In tertiary syphilis, the miotic Argyll Robertson pupil reacts poorly to light but briskly to accommodation. Treatment is as for the systemic disease.

STRUCTURAL AND AGE-RELATED DISORDERS

Cataract

A cataract is an opacification of the crystalline lens. The lens doubles in volume between birth and age 70 years as new lens "fiber cells" are laid down on the external aspect of the lens cortex, beneath the lens capsule. The older fibers in the center of the lens cannot be desquamated into the surrounding aqueous and thus are compressed into the center of the lens. At birth, the lens is pliable and totally transparent. By age 45 years, the lens loses its pliability, which compromises near vision. As the process progresses, the lens loses its transparency, beginning at the center of the lens (nuclear sclerosis). The concurrent change in density of the lens nucleus may alter the optical characteristics of the eye to cause acquired nearsightedness ("second sight"). Ultimately, the cataract may become so dense that cataract surgery is necessary to restore vision.

Symptoms are typically loss of vision, especially at night, and glare. Cataract surgery, performed as an outpatient, is elective and depends on how much the decreased vision interferes with the normal lifestyle of the patient. A synthetic intraocular lens implant is inserted into the eye during surgery. Prognosis for restoration of vision is excellent, depending on the function of the retina. In general, cataracts develop asymmetrically. The worst eye (vision-wise) should have surgery first. As the second eye's cataract worsens, decreasing vision and monocularity are indications for cataract surgery in the second eye.

Glaucoma

Glaucoma results from an imbalance between the production of aqueous fluid and the drainage of aqueous fluid. The aqueous is produced by the nonpigmented ciliary epithelium of the pars plicata of the ciliary body. Aqueous fluid leaves the eye through the trabecular meshwork into the venous circulation. If the drainage function does not match the production potential, the intraocular pressure increases. If the elevated intraocular pressure is high enough or is present long enough, ganglion cells in the retina are damaged, causing loss of their axons. Loss of axons can best be appreciated clinically at their normal exit from the eye, the optic disc. Bulk loss of axons will lead to enlargement of the optic cup, which is recorded as increase in the cup-to-disc ratio.

In open-angle glaucoma, there is apparent free anatomic access to the trabecular meshwork. In closed-angle glaucoma, there is a relative or absolute anatomic barrier to the flow of aqueous.

CHRONIC OPEN-ANGLE GLAUCOMA

The most common type of glaucoma in elderly people is chronic open-angle glaucoma. The first symptom is loss of peripheral visual fields with retention of central visual function. The visual field may be reduced considerably before the patient notes loss of function. Most cases of chronic open-angle glaucoma are identified during routine eye examinations, either by discovery of abnormally high intraocular pressure or by the presence of a high cup-to-disc ratio (Fig. 431-20). Normal intraocular pressure is generally at or below 21 mm Hg, but exceptions exist depending on corneal thickness (influencing artifacts of measurement) and genetic disposition. The diagnosis of glaucoma is confirmed by characteristic visual field loss as determined by automated perimetry.

The treatment goal is to reduce intraocular pressure, initially with pharmacologic agents: β-blockers (e.g., betaxolol drops 0.5% twice daily), carbonic anhydrase inhibitors (e.g., dorzolamide drops twice daily), α-agonists (e.g., apraclonidine drops twice daily), and antiprostaglandins (e.g., latanoprost drops twice daily). Generally, the drops are taken for a lifetime. Applying energy to the structures of the trabecular meshwork with a laser (laser trabeculoplasty) often results in years of control of intraocular pressure. In resistant cases, mechanical filtration is accomplished surgically by bypassing the trabecular meshwork either by creating a fistula (trabeculectomy) between the anterior chamber and the episcleral tissue or by implanting a synthetic filtration device (a tube-shunt) from the anterior chamber through the sclera

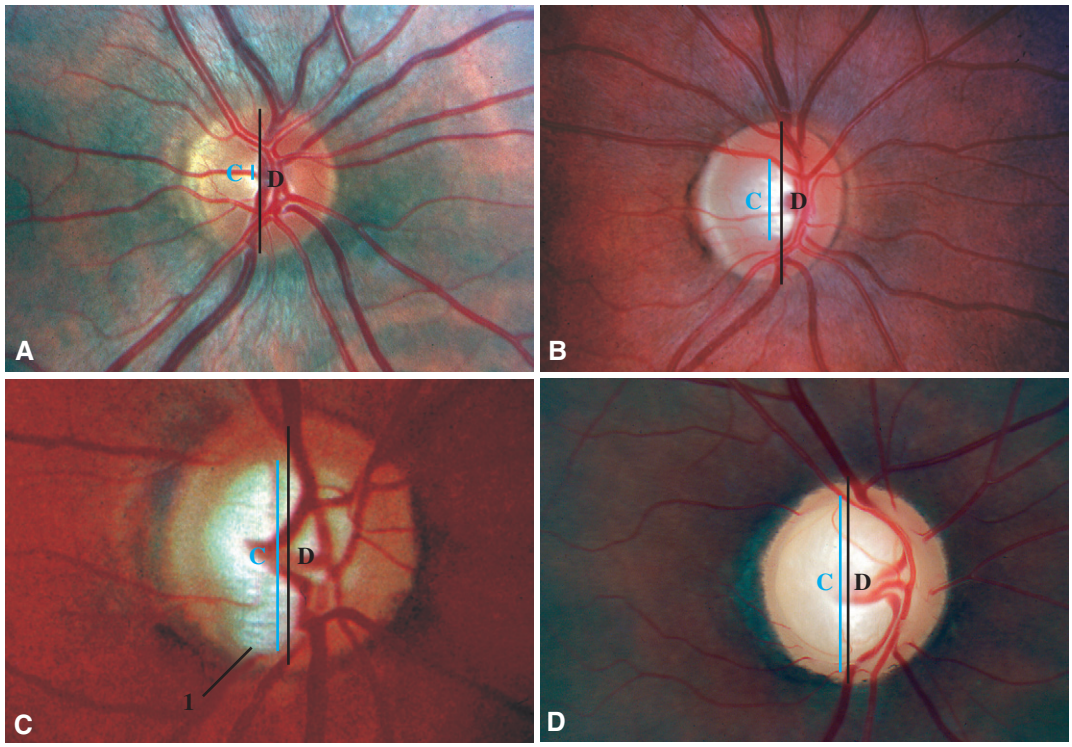

FIGURE 431-20. Cup-to-disc ratios. A, Normal cup-to-disc (C/D) ratio of 0.1. **B,** Likely normal C/D ratio of 0.5. **C,** C/D ratio of 0.8 vertically with inferior notching (1) of the nerve (glaucomatous change). **D,** C/D ratio of 0.90 vertically (glaucomatous change). into a collection reservoir located at the equator of the eye in the soft tissues of the orbit.

PSEUDOEXFOLIATIVE GLAUCOMA

Pseudoexfoliative glaucoma syndrome is a genetically determined biochemical abnormality of the basement membrane protein, fibrillin. The syndrome occurs among people throughout the world but is especially prominent in Scandinavians and Saudi Arabians. Affected individuals are identified by accumulation of abnormal fibrillin (exfoliative material) on the surface of the crystalline lens, most easily seen in the pupillary space. Pseudoexfoliative glaucoma increases the risk of developing open-angle glaucoma five-fold, to a lifetime risk of about 10%. Treatment is as for open-angle glaucoma.

ANGLE-CLOSURE GLAUCOMA

Angle-closure glaucoma (Fig. 431-21) may occur over a short period of time and cause extreme debilitating symptoms. Alternatively, symptoms may develop over a long period of time with few specific symptoms.

The risk factors for angle-closure glaucoma closure are based on the anatomic configuration of the components of anterior chamber. Persons who are farsighted (hyperopia) have a shortened anterior-to-posterior axis of the eye, indicated clinically by a shallow anterior chamber. As the crystalline lens increases in volume with time, the iris is displaced anteriorly. At some point, the posterior surface of the iris may come in relatively tight contact with the anterior surface of the lens. Aqueous flow is restricted, and fluid accumulates in the posterior chamber, where it displaces the diaphanous peripheral iris anteriorly. When the peripheral iris comes in contact with the posterior cornea, the anterior chamber angle is suddenly occluded. Angle closure may be precipitated by pharmacologic dilation of the pupil. Patients who are farsighted (hyperopia) or have cataracts should be dilated with caution. The intraocular pressure may increase from 21 mm Hg to 50 to 70 mm Hg (nearly equaling diastolic arterial pressure). The symptoms of acute angle closure may include extreme pain, which may be poorly localized to the eye, nausea, and vomiting. Persistent vomiting may cause abdominal pain, simulating an acute abdomen.

Initial treatment is with topical (e.g., timolol 0.5% in one dose) and systemic pressure-lowering agents (e.g., carbonic acetazolamide, 250 to 500 mg intravenously or two 250-mg tablets orally in one dose if intravenous access or drug is not available), followed by creation of a fistula in the peripheral iris with a laser (YAG laser iridectomy) between the posterior chamber and the anterior chamber to bypass the obstruction. Most patients require a laser iridectomy prophylactically in the second eye to prevent angle-closure glaucoma.

Secondary glaucoma may also occur after intraocular hemorrhage, intraocular trauma, and intraocular inflammation. Some developmentally related secondary glaucomas, such as the iridocorneal endothelial syndrome, may not become evident until adulthood.

Retinal Detachment

A retinal detachment is a separation of the neural (sensory) retina from the retinal pigment epithelium. The two main types are rhegmatogenous, caused by a retinal hole, as may occur with a posterior vitreous detachment, and nonrhegmatogenous, caused by traction, such as in proliferative diabetic retinopathy or by fluid accumulation under neural retina in conditions such as malignant hypertension or eclampsia of pregnancy.

The classic symptoms are a sensation of flashes of light, floaters in the field of the involved eye owing to the causative vitreous detachment, and a shadow. Urgent treatment usually is needed. Some small peripheral rhegmatogenous detachments may be treated by laser, but larger ones and traction retinal detachments are treated by more extensive surgery (scleral buckle surgery or vitreous surgery). In serous retinal detachment, the underlying condition should be treated.

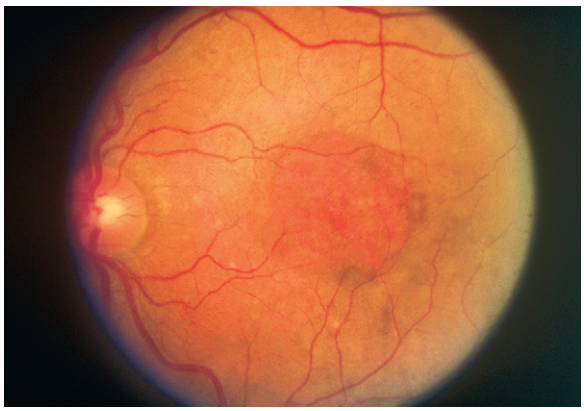

FIGURE 431-22. Dry age-related macular degeneration. Drusen are present in the posterior pole around a large area of geographic atrophy of the retinal pigment epithelium.

Age-Related Macular Degeneration

Age-related macular degeneration is a neurodegenerative disease that affects the junction between the neural retina and the retinal pigment epithelium, mainly in the sixth to ninth decades of life. About 8.5% of the world's blindness is caused by age-related macular degeneration, mainly in industrialized countries. In the United States, age-related macular degeneration affects more than 1.75 million persons, and its prevalence increases with each decade after the age of 55 years. The genetic influence of age-related macular degeneration has not yet been determined, but abnormalities of complement factor H may play a role. Environmental factors such as smoking are known to accelerate this degenerative process.

Two types predominate: the "dry" or geographic type, and the "wet" or neovascular type. The wet type causes the most profound vision loss but is less common than the dry type.

The first sign of age-related macular degeneration is variation of the character and density of the retinal pigment epithelial pigment (pigment dropout) in the posterior region of the retina, the macula. The pathologic process causes abnormal protein (lipofuscin) to accumulate between the retinal pigment epithelial cells and its basement membrane complex (Bruch's membrane), designated as drusen. The drusen of macular degeneration (soft drusen) are small (30 μm), hypopigmented, poorly defined areas in the deep retina. This stage, called dry age-related macular degeneration, may antedate subjective alteration in vision by several decades. The anticipated rate of progression is difficult to determine in individual cases.

The first symptom of age-related macular degeneration is loss of vision. Loss of vision corresponds with loss of photoreceptor outer segments. The effect is in the exact center of the most sensitive portion of the retina, the fovea. The peripheral retina is not involved. As the process progresses, individuals with advanced disease will be able to walk down a street without apparent difficulty (a peripheral retinal function) but will not be able to recognize facial features of people whom they meet (a macular retinal function). Visual aids and other devices, such as special glasses and television aids, may allow patients to continue with daily functions and to continue to live independently. This phase of the process, the "dry phase," advances at a slow rate (months to decades), during which patients develop retinal features of well-defined pigment loss (geographic retinal atrophy; Fig. 431-22). No current treatment exists for the dry phase of the disease, except for a possible positive influence of dietary supplements (antioxidants). Vitamin supplementation with vitamins C and E, β-carotene, zinc, and copper may retard the progression of moderate age-related macular degeneration to severe age-related macular degeneration.■ β-Carotene (a vitamin A precursor) of this quantity is not recommended for cigarette smokers because of an increased risk for lung cancer. Cessation of smoking, control of blood sugar, control of blood lipid levels, and control of systemic blood pressure are particularly important behavioral modifications.

In the "wet phase" of age-related macular degeneration (Fig. 431-23), frail, neovascular channels originating from the established vascular system of the choroid may extend through a breach in Bruch's membrane into the

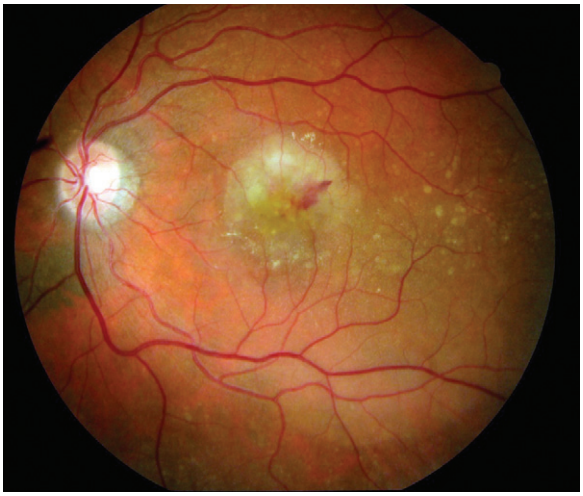

FIGURE 431-23. Wet age-related macular degeneration. A "dirty gray" neovascular membrane is present under the central macular area.

FIGURE 431-24. Background diabetic retinopathy. Exudates, microaneurysms, and small hemorrhages are seen in the posterior pole (right eye).

subretinal space (subretinal neovascularization). Spontaneous hemorrhage of the vessels adds to photoreceptor loss. Hemorrhage is accompanied by acute, and usually permanent, loss of central visual acuity (i.e., the wet phase of age-related macular degeneration). Both eyes are usually affected to a similar degree. Neovascularization can be identified by fluorescein angiography and OCT. Intraocular injections of antivascular endothelial growth factors (e.g., ranibizumab) reduce the risk for visual loss in patients with neovascular age-related macular degeneration and can result in gains in vision.[1] Other treatments include argon laser photocoagulation or, in advanced cases, vitrectomy to remove subretinal neovascular membranes.

SYSTEMIC DISEASES WITH OCULAR SYMPTOMS DURING ADULTHOOD

Diabetes Mellitus

Diabetic retinopathy is one of the leading causes of blindness in the United States. More than 75% of the blind are women. Background diabetic retinopathy, with microaneurysms, hemorrhages, exudates (Fig. 431-24), and macular edema, accounts for most cases of decreased vision, but rarely causes profound vision loss. Most diabetic patients never develop the more severe proliferative diabetic retinopathy (Fig. 431-25), which generally occurs only after 15 years or more of diabetes and causes a profound loss of vision.

Diabetic retinopathy is closely correlated with the duration of diabetes mellitus (Chapter 236). The prevalence of diabetic retinopathy is about 27% among patients who have had type 1 diabetes for 5 to 10 years, 70 to 90% among patients who have had diabetes for more than 10 years, and 95% among patients who have had diabetes for 20 to 30 years. In patients with type 2 diabetes (Chapter 237), the prevalence of diabetic retinopathy is about 23% after 12 years and 60% after 16 years. Tight control of blood

FIGURE 431-25. Severe proliferative diabetic retinopathy with cotton-wool spots, intraretinal microvascular abnormalities, and venous bleeding. (From Yanoff M, Duker JS, eds. *Ophthalmology.* Philadelphia: Mosby Elsevier; 2009.)

FIGURE 431-26. Hypertension retinopathy with narrowed arterioles whose sclerosed walls create the appearance of "nicking" when the arterioles cross venules. (From Yanoff M, Duker JS, eds. *Ophthalmology.* Philadelphia: Mosby Elsevier; 2009.)

glucose greatly reduced the risk for the development of diabetic retinopathy.

The treatment of diabetic retinopathy includes control of the diabetes and any hyperlipidemia,[2] laser therapy for background diabetic retinopathy,[3] and laser or surgical therapy to treat proliferative diabetic retinopathy.[4] Timely laser therapy of macular edema can reduce severe vision loss by 95%, and intravitreal steroid injection is also beneficial.[5] The benefit of antiangiogenic therapy is less clear.[6] With acute hyperglycemia, accumulation of sorbitol may lead to lenticular swelling; secondary refractive errors may persist for 6 to 8 weeks.

Hypertension

In chronic hypertension (Chapter 67), the characteristic retinal vascular findings can assess the severity of hypertension. As the severity increases, patients develop arterial narrowing, arteriovenous nicking (Fig. 431-26), nerve fiber layer infarcts, and intraretinal hemorrhages. Moderately sclerosed arterioles have a "copper wiring" appearance, whereas severely sclerosed vessels demonstrate "silver wiring." Acute hypertension may cause optic nerve edema ("papilledema"; Fig. 431-27) and serous retinal detachments that usually resolve without significant sequelae if blood pressure is controlled.

Other Systemic Diseases

In bacterial endocarditis (Chapter 76), emboli may cause conjunctival hemorrhages or the characteristic Roth's spot (Fig. 431-28). Accumulation of copper in the posterior cornea may aid in the diagnosis of Wilson's disease (Chapter 218), although its clinical diagnosis usually precedes the characteristic Kayser-Fleischer ring (see Fig. 218-1 in Chapter 218), which fades after treatment. Tay-Sachs and Niemann-Pick diseases (Chapter 215) are associated with a foveal cherry-red spot owing to the accumulation of gangliosides within perifoveal ganglion cells. Pseudoxanthoma elasticum (Chapter 268) is often associated with characteristic angioid streaks of the retina.

VASCULAR ABNORMALITIES OF THE EYE

The major vessels of the retina enter the eye at a point of relative constriction in the tissues of the lamina cribrosa of the optic disc. In persons who have

FIGURE 431-27. Papilledema. (Courtesy of Dr. Kathleen Digre.)

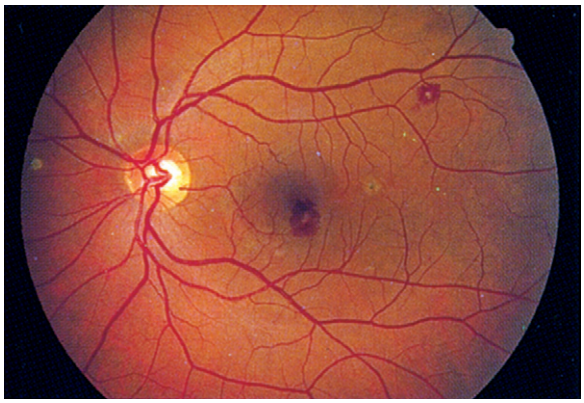

FIGURE 431-28. Roth's spots. Multiple white-centered hemorrhages in a man with recurrent subacute bacterial endocarditis. White-centered hemorrhages are also seen with leukemia and diabetes. The small white scars are probably the residua of previous episodes.

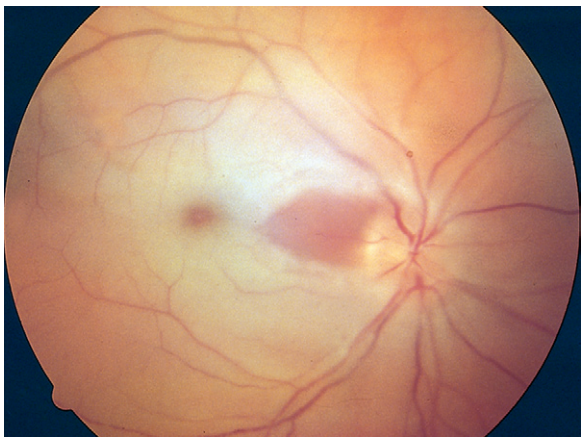

FIGURE 431-29. Central retinal artery occlusion. Fundus photograph shows diffuse retinal edema. The heavily pigmented fovea with its uniquely thin inner retina produces a cherry-red spot against the dusky macula. In this case, a small area of retina adjacent to the optic disc is spared, owing to the presence of a cilioretinal artery.

generalized vascular disease, particularly systemic hypertension, occlusion of either the artery or vein may lead to a sudden loss of vision. Partial occlusion of either the artery or vein is associated with less visual loss but still increases the risk of developing neovascular glaucoma.

Arterial occlusion of the central retinal artery (Fig. 431-29) presents as painless acute loss of vision. The ischemic posterior retina generally has a pale gray appearance except at the fovea, where the normal color is preserved (cherry-red spot). The clinical appearance of edema resolves over time, but vision generally does not recover.

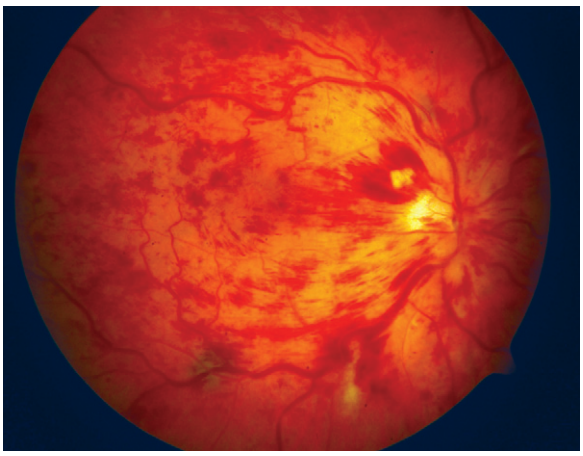

FIGURE 431-30. Central retinal vein occlusion with diffuse intraretinal hemorrhages in all four quadrants.

Venous occlusion of the central retinal vein (Fig. 431-30) presents as painless loss of vision. The retina, however, is characterized by extreme, generalized hemorrhages, which resolve very slowly and are often associated with opaque areas of focal retinal ischemia (cotton-wool spots). This process destroys the full-thickness of the retina. Usually, no vision returns. Central vein occlusion is associated with a major risk of developing secondary neovascular glaucoma.

Giant cell arteritis (temporal arteritis [Chapter 279]) is occlusion of the blood supply of the optic disc by inflammation of the short posterior ciliary arteries. Occlusion causes acute, painless loss of vision. Presenting symptoms before visual loss often include a vague sensation of fatigue, scalp tenderness, or jaw claudication. Diagnosis is suspected by classic characteristics and by an elevated erythrocyte sedimentation rate or elevated C-reactive protein level. Histologic confirmation is provided by a biopsy showing granulomatous inflammation in the region of the internal elastic lamina of the temporal artery. Emergent treatment, often protracted, with systemic steroids (Chapter 279) can prevent vascular occlusion and visual loss, but lost vision is not usually restored by treatment. There is a significant risk of the process developing in the second eye.

Nonarteritic optic neuropathy is caused by occlusion of the posterior ciliary arteries and infarction of the optic disc, resulting in acute, usually unilateral, painless loss of vision. There often are no antecedent symptoms except those systemic signs and symptoms associated with systemic nonarteritic vascular disease such as systemic hypertension. Occlusion is thought to be due to atherosclerosis or some other lumen-compromising mechanism. No treatment restores vision. There is a risk for the same process affecting the second eye.

IDIOPATHIC INFLAMMATORY AND AUTOIMMUNE DISORDERS

Ocular or periocular tissues may be the primary focus of isolated idiopathic or autoimmune inflammation. Pain is common, and changes in vision may occur.

Keratoconjunctivitis Sicca

Keratoconjunctivitis sicca, or the dry eye syndrome, results from deficiency of any of the tear film layers. Symptoms include gritty, foreign body sensations, burning, photophobia, and decreased visual acuity. Idiopathic inflammation in keratoconjunctivitis sicca and xerostomia represents Sjögren's syndrome (Chapter 276). Recurrent corneal erosion, keratitis, and corneal opacification can occur. Many medications can also cause dry eyes (Table 431-8).

Artificial tears, up to four times daily, and lubricating ointments are helpful. Corticosteroids (e.g., loteprednol 0.5% eyedrops four times a day) are also effective as an initial treatment. Cyclosporine eyedrops (0.05%, one drop in each eye every 12 hours) are useful when other measures fail.

TABLE 431-8 PARTIAL LIST OF SYSTEMIC MEDICATIONS CAUSING DRY EYE

MEDICATION	CLASS
Ibuprofen	Nonsteroidal anti-inflammatory
Diphenhydramine	Antihistamine
Triprolidine	Antihistamine
Chlorpheniramine	Antihistamine
Atenolol	β-Blocker
Metoprolol	β-Blocker
Propranolol	β-Blocker
Clonidine	α-Agonist
Scopolamine	Anticholinergic
Amiodarone	Antiarrhythmic
Thiabendazole	Antinematode
Isotretinoin*	Retinoid

*Severe, long-term dry eye with onset up to several years after treatment. All others tend to abate with cessation.
From Goldman L, Ausiello DA, eds. *Cecil Textbook of Medicine*, 23rd ed. Philadelphia: Saunders Elsevier; 2008:2852.

Scleritis

Episcleritis, which is an inflammation immediately underlying the conjunctiva, is distinguished from conjunctivitis because its radially oriented vessels do not move with the conjunctiva. Mild pain may be present. Episcleritis is self-limited. Instillation of 2.5% phenylephrine is helpful in making the diagnosis because it causes blanching in episcleritis but not in scleritis. Oral or topical nonsteroidal anti-inflammatory medications such as flurbiprofen or diclofenac may hasten resolution.

Scleritis, which presents as severe pain and redness, is associated with infectious or autoimmune connective tissue disease in about 50% of cases. Vision may be reduced if the posterior sclera is involved. Diffuse or sectoral hyperemia is nonmobile and does not blanch with instillation of phenylephrine. Secondary uveitis and keratitis may occur. Diagnostic evaluation includes ultrasonography or magnetic resonance imaging and laboratory tests to identify potential underlying conditions. Treatment may require topical or oral nonsteroidal anti-inflammatory medications or corticosteroids.

Mooren's Ulcer

Mooren's ulcer is idiopathic, progressive, peripheral corneal thinning, likely autoimmune. It can be unilateral or bilateral, and pain is common. Topical corticosteroids, mucolytics, and cytotoxic agents have been used. Bandage contact lenses and conjunctival recession or advancement have also been used with variable success.

Orbital Pseudotumor

Nonspecific, idiopathic orbital inflammation involving the lacrimal gland (dacryoadenitis), extraocular muscles (myositis), orbital fat, sclera, or optic nerve sheath (optic perineuritis) can be caused by orbital pseudotumor. Pain is frequent. Patients may present with proptosis, limited ocular movements, or decreased acuity. OCT or magnetic resonance imaging excludes a mass lesion. Patients respond dramatically to systemic corticosteroids within 24 hours, but the steroids must be tapered slowly over months to prevent recurrence.

Iritis

Iritis presents with pain, photophobia, and blurred vision, with about 50% of cases related to systemic disease. Slit lamp examination shows inflammatory cells and protein exudate in the anterior chamber. Symptomatic treatment is with prednisolone acetate 1% suspension four times a day and cycloplegic drugs (cyclopentolate 1 or 2% twice daily) is usually effective, but repeated episodes require evaluation for autoimmune and infectious causes.

Rheumatoid Arthritis

Juvenile rheumatoid arthritis (Chapter 272) is the most common specific childhood entity associated with uveitis. In adults, the ocular manifestations of rheumatoid arthritis mainly affect the anterior part of the eye, cornea, and sclera. Nearly 50% of patients who have peripheral ulcerative keratitis of the cornea have an associated systemic disease, mainly collagen vascular disease, and especially rheumatoid arthritis. Similarly, almost half of patients who have scleritis have an associated systemic disease, and about 15% of these are connective tissue diseases. Scleromalacia perforans, which is aseptic necrosis of the sclera, is associated with rheumatoid arthritis about 46% of the time.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (Chapter 274) causes eye manifestations from both the primary disease and its treatment with derivatives of chloroquine. The retina may show a retinal vasculitis, and the optic nerve an optic neuritis, ischemic or nonischemic. Chloroquine therapy can cause a toxic retinal degeneration, but this complication is rare if the daily dose of chloroquine does not exceed 250 mg (and 6.5 mg/kg of body weight for hydroxychloroquine).

Sarcoidosis

About 25% of patients with sarcoidosis (Chapter 95) develop chronic uveitis. Sarcoid also can involve the lids, conjunctiva, optic nerve, cranial nerves, and lacrimal glands. Anterior uveitis is treated topically with prednisolone acetate in decreasing doses, depending on degree of inflammation, and with daily cycloplegics (cyclopentolate 2%, atropine 1%). Posterior uveitis, dacryoadenitis, and neurologic manifestations require systemic corticosteroids, but the doses have not been standardized.

Sympathetic Ophthalmia

Sympathetic ophthalmia is an autoimmune disease characterized by bilateral, granulomatous uveitis following trauma to one eye. The condition is very rare, occurring in less than 1 per 10,000 cases of ocular surgical procedures and 1 per 1000 cases of accidental trauma.

The identified antigen within the eye is thought to be located in the outer retina. The disease is recognized clinically by signs of inflammation in the uninjured eye, about 2 weeks after the injury. Generally, removal of the injured eye within these 2 weeks will protect against the development of sympathetic ophthalmia in the uninjured eye, but once the uninjured eye is involved, removal of the originally injured eye will not influence the process. Left untreated, inflammation may destroy the function of both eyes. Once sympathetic ophthalmia is established, the patient will require anti-inflammation treatment (e.g., prednisolone, 1.0 to 1.5 mg/kg orally per day), most likely for an extended period.

GENETICALLY DETERMINED DISEASES THAT MAY BECOME SYMPTOMATIC DURING ADULTHOOD

Corneal Stromal Dystrophy

Most corneal dystrophies are autosomal dominant and bilateral, progress slowly, and primarily affect one layer of an otherwise normal cornea. Common types of dystrophies are anterior basement membrane, macular, granular, lattice, and Fuchs' endothelial. Some result from mutations within the same gene. For example, the *BIGH3* on 5q31 is associated with granular and lattice dystrophy and corneal dystrophy of Bowman. The main symptom, caused by opaque corneal deposits, is blurred vision. If the decreased vision interferes with activities of normal living, a corneal transplantation can be performed.

Choroidal Dystrophy

Choroidal dystrophies are progressive, inherited disorders characterized by atrophy of the retinal pigment epithelium and choroid. The main entities are central areolar choroidal sclerosis (autosomal dominant or recessive), gyrate atrophy (deficiency of the mitochondrial matrix enzyme ornithine-δ-aminotransferase), and choroideremia (deficiency of component A of Rab geranylgeranyl transferase). No treatment exists for central areolar choroidal sclerosis or choroideremia. An arginine-restricted diet may be helpful in treating gyrate atrophy.

Retinitis Pigmentosa

Retinitis pigmentosa (Fig. 431-31) is bilateral and symmetrical, starts in early adult life, and is progressive. Retinitis pigmentosa can be an autosomal dominant or recessive disease, X-linked, digenic, mitochondrial, or sporadic. The primary defect, apoptotic in nature, appears to be in the neural retinal receptors. The main findings consist of the tetrad of bone-corpuscular retinal pigmentation; a pale, waxy optic nerve; attenuation of retinal arterioles; and a

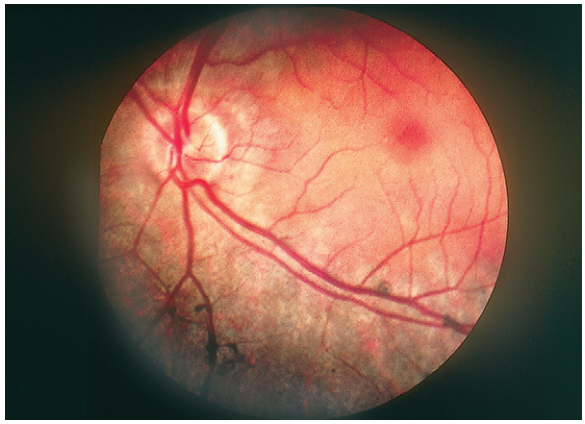

FIGURE 431-31. Retinitis pigmentosa. Fundus photograph shows "bone spicule" pigmentation of the midperipheral fundus, waxy pallor of the optic disc, and attenuated retinal vessels, the most consistent finding in retinitis pigmentosa. (Courtesy of Dr. John I. Loewenstein.)

posterior subcapsular cataract. Night blindness is the primary symptom. The electroretinogram usually shows no electrical evidence of retinal function. Vitamin A palmitate supplementation (15,000 IU daily) may slow the rate of progression. Gene therapy is under investigation.

COMMON PEDIATRIC OR ADOLESCENT DISEASES THAT MAY PERSIST INTO ADULTHOOD

Retinopathy of Prematurity

The peripheral retina, particularly the temporal retina, is not vascularized in premature infants (36 weeks or younger). In the premature infant, vessels of the immature retina may leave the plane of the retina and grow into the adjacent vitreous body, where tractional forces can cause total, irreversible retinal detachment. The detached retina forms a mass of fibrovascular tissue posterior to the crystalline lens, explaining the original name of this condition, retrolental fibroplasia. The primary risk factor for retinopathy of prematurity is the degree of prematurity of the infant and the use of supplemental oxygen. Early recognition and treatment of retinal neovascularization aid in reestablishing normal retinal vascular development.

Hemangioma of the Eyelid

Hemangioma of the eyelid is a hamartomatous (tissue normally found in the area) malformation of vessels in the soft tissues of the eyelid. The abnormal vascular channel, which may not be clinically evident until several weeks after birth, can expand to enlarge the eyelid and cause mechanical ptosis. Eyelid hemangioma may involute over time, usually in 4 to 7 years, but in the interval there is risk of developing amblyopia. Treatment includes intralesional steroid injection, laser photocoagulation, and, rarely, surgical debulking.

Congenital Cataract

Opacification of the crystalline lens occurs in many developmental and biochemical abnormalities. In congenital rubella (Chapter 376), the opacity is relatively limited to the fetal nucleus and has a pearl-like density. Cataract extraction is essential for dense cataracts of any type if amblyopia is to be prevented, but liberation of live rubella virus into the eye during cataract surgery may lead to necrotizing endophthalmitis and loss of the eye.

The cataract of galactosemia (Chapter 212) is potentially reversible with dietary restriction of galactose. Most other congenital cataracts do not progress. The degree of vision, which may be surprisingly adequate, cannot be accurately predicted by the clinical appearance of a lens opacity.

TUMORS OF THE EYE

Retinoblastoma

Retinoblastoma, the most common intraocular malignant tumor of childhood, results from uncontrolled proliferation of retinoblasts, which are pluripotential neuroectodermal cells that will differentiate into the various components of mature retina. A genetic deletion of the *RB* (retinoblastoma) gene occurs in the chromosomal region 13q14. The tumor initially proliferates in the plane of the retina but is capable of involving all structures within the eye. Retinoblastoma may spread to the central nervous system through the optic nerve and through blood vessels to tissues at distant sites.

Approximately 40% of cases of retinoblastoma are heritable and generally diagnosed before age 12 months, much earlier than the nonheritable form. In 80% of heritable retinoblastomas, retinal tumors are multiple in each eye and are bilateral. These patients have a significant risk of developing a secondary primary malignant tumor (e.g., osteogenic sarcoma).

The nonheritable, sporadic form arises spontaneously and represents about 60% of cases. The average age at presentation is 24 months. Generally only a single tumor occurs in one eye, unlike the heritable form, in which multiple tumors in one eye and bilateral tumors are common. No detectable chromosomal abnormality is present, so the risk for retinoblastoma in succeeding generations is low. These children have the same risk for second primary tumors as the general population.

Retinoblastoma is often discovered by parents or relatives who notice a light reflex in one eye relative to the other either (white or "cat's eye" reflex; leukokoria). Children with retinoblastoma also may present with strabismus, iris neovascularization, dilated fixed pupil, secondary glaucoma, or tumor accumulation in the anterior chamber (neoplastic hypopyon). More advanced cases may present with signs of intraocular inflammation or ruptured globe with orbital extension. In some of cases of regressed retinoblastoma, the sole clinical sign may be a small, calcified tumor in the plane of the retina with surrounding retinal pigment epithelial scarring.

Most children are treated with chemotherapy, sometimes also with intraocular laser therapy or radiation, or both. Enucleation is used for advanced cases with no visual potential.

Malignant Melanoma

Malignant melanoma (Chapter 210) of the conjunctiva is rare. The individuals at risk are middle aged and lightly pigmented. Melanoma of the conjunctiva may arise from a preexisting nevus or de novo, but most arise from unilateral, acquired, variably pigmented regional, flat, or slightly elevated lesions in which the degree and distribution of pigmentation tend to vary over time. The regions of greatest risk are the conjunctiva at the limbus (junction of cornea and sclera), in the conjunctival fornix (deep peripheral recesses of the conjunctiva), and in the caruncle (elevated nodule between the nasal lid margins). Extensions onto the corneal surface or formation of a nodule or loss of pigmentation are indications for biopsy. Proliferation and hyperpigmentation of melanocytes without nuclear or cellular atypia is not associated with progression to melanoma, whereas associated nuclear or cellular atypia, particularly coupled with mitotic activity, is highly linked with progression to melanoma. Frank melanoma with a thickness of more than 0.8 mm is a risk factor for metastatic melanoma. Treatment is surgical excision, often supplemented with cryoablation. The long-term outcome is less favorable than for cutaneous melanoma because the tumor may metastasize early when the primary tumor is very small (e.g., 2 mm).

Malignant melanoma of the uveal tract is the most common primary intraocular malignancy of adults, but its incidence is only 2 to 6 per 1 million per year in high-risk populations (blue-eyed white people). The tumor, which arises from preexisting nevi or dendritic melanocytes anywhere in the uveal tract, is almost always unilateral, unicentric, and nodular and is usually diagnosed at an asymptomatic phase during routine screening examination of the dilated fundus. Symptomatic tumors arise near sensitive portions of the retina (e.g., the macula) or cause retinal detachment or cystoid macular edema. Iris tumors (Fig. 431-32) are generally pigmented and elevated above the surrounding contour, where they are recognized early in their course. Posterior tumors may be completely amelanotic and occasionally may have a bilobed appearance. Accuracy in diagnosing melanoma of the uveal tract by clinical means alone is greater than 98%. Treatment is controversial; options include enucleation of the eye, external beam and plaque (iodine-125) radiation, and en bloc resection. The overall survival rate is approximately 50% at 15 years. Risk factors for metastasis, most commonly to the liver, include tumor size, cell type, angiogenic mimicry, and the presence of monosomy 3 in the tumor cells.

Orbital Tumors

Primary tumors in the orbit of adults include cavernous hemangioma, schwannomas, and various proliferations of fibrous tissue (solitary fibrous tumor). Rhabdomyosarcoma may arise from ectopic rests of mesenchyme rather than from mature rectus muscle. Orbital tumors usually are diagnosed by imaging techniques. The treatment is orbital exploration and surgical removal.

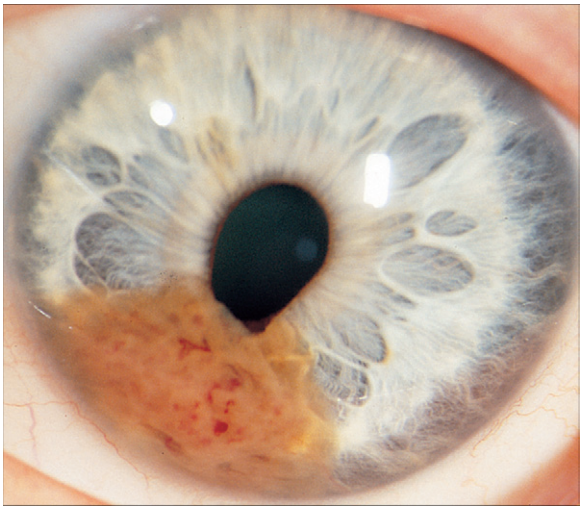

FIGURE 431-32. Iris melanoma that has prominent intrinsic blood vessels. Note peaking of the pupil toward the tumor. (From Yanoff M, Duker JS, eds. *Ophthalmology.* Philadelphia: Mosby Elsevier; 2009.)

Lymphoma

Orbital and conjunctival lymphomas are usually small B-cell mucosa-associated lymphoid tissue tumors (Chapter 191). Approximately 50% of cases ultimately include systemic disease that may, however, be delayed by decades. External beam radiation is used to treat isolated periocular disease, whereas systemic chemotherapy is required for systemic involvement.

Large-cell B-cell lymphoma (Chapter 191) may present in the eye as a form of vitreitis (cells suspended in the vitreous) or a subretinal or intraretinal infiltrate before it is discovered in the central nervous system. The diagnosis may be verified by cytologic examination of vitrectomy specimens. Treatment is generally systemic, but the outcome is usually poor.

The eye may infrequently be involved in multiple myeloma (Chapter 193). Retinal hemorrhages and vitreous opacification may occur. Periorbital osteolytic lesions of bone may be present.

Lacrimal Gland Tumors

Epithelial lacrimal gland neoplasms may arise in the lacrimal gland. The lacrimal gland contains a resting population of non-nodal lymphocytes and is a second common site for lymphomas. Malignant epithelial tumors (adenoid cystic carcinoma) may metastasize at an early stage through perineural spaces of large peripheral nerves to adjacent bone. Most epithelial gland tumors are treated with total surgical removal of the lacrimal gland because of the risk for recurrence and malignant transformation of residual tumor.

Ocular Metastasis

Metastasis to the orbit in adults is very uncommon because of its relatively small vascular volume. Metastasis to the rectus muscles present with adult-onset strabismus. Metastasis to the orbit is more common in childhood than adult leukemia.

Metastasis to the uveal tract is common, especially from primary breast and lung tumors. Metastatic lesions often grow rapidly and disturb visual function; serous retinal detachment is common.

OCULAR EFFECTS OF SYSTEMIC MEDICATIONS

Innumerable medications may cause ocular side effects (Table 431-9). Therefore, patients taking systemic medications often require periodic surveillance to identify ocular toxicity.

Chloroquine and *hydroxychloroquine* may cause decreased color vision and visual field defects at high doses. Chloroquine toxicity is thought to occur after a cumulative dose of 300 g, whereas hydroxychloroquine may cause symptoms after long-term maintenance of 750 mg/day. The macular portion of the fundus develops a typical bull's-eye pattern. Corneal whorls may be seen. Symptoms are not reversible and tend to progress after drug cessation. Annual fundus examination with color testing, macular function tests, and automated visual field test may be indicated.

TABLE 431-9 SYSTEMIC MEDICATIONS WITH OCULAR EFFECTS

AGENT	EFFECT
Chloroquine	Dyschromatopsia, visual field defects
Hydroxychloroquine	Dyschromatopsia, visual field defects
Thioridazine	Blurred vision
Chlorpromazine	Blurred vision
Digoxin	Yellow vision
Ethambutol	Optic neuritis
Amiodarone	Corneal whorls, pigmentary retinopathy
Corticosteroids	Glaucoma, cataract
Plaquenil	Pigmentary maculopathy
Tamoxifen	Retinopathy
Neuroleptics	Nystagmus
Compazine	Oculogyric crisis
Vitamin A	Pseudotumor cerebri
5-Fluorouracil	Canalicular stenosis (tearing)
Isotretinoin	Severe dry eye (long-term effect)

From Goldman L, Ausiello DA, eds. *Cecil Textbook of Medicine*, 23rd ed. Philadelphia: Saunders Elsevier; 2008:2852.

Pigmentary maculopathy may arise as blurred vision in patients taking *thioridazine* or *chlorpromazine.* Approximately 800 mg/day of the former or 1200 mg/day of the latter is believed sufficient to cause toxicity. Patients should be examined every 6 months.

Any of the commonly used antituberculous medications may cause optic neuropathy, although *ethambutol* carries the greatest risk. Pupillary response, color vision, acuity, and visual fields are the clinical parameters used to assess optic nerve function.

Cornea verticillata may be seen in patients taking *amiodarone* because of lysosomal accumulations within the epithelial basement membrane. *Fabry's disease* produces similar changes, as can other medications. Corneal whorls are usually reversible when caused by drug toxicity, and they rarely interfere with vision.

432 NEURO-OPHTHALMOLOGY

ROBERT W. BALOH AND JOANNA JEN

A mechanistic understanding of vision impairment along with disturbances in pupillary and oculomotor control lies close to the heart of diagnosing neurologic disorders.

VISION

One of the most difficult diagnostic problems is vision loss that cannot be explained by obvious abnormalities of the eye. To evaluate such a patient properly, the examining physician must be familiar with the anatomy and physiology of the afferent visual system. The afferent visual pathways cross the major ascending sensory and descending motor systems of the cerebral hemispheres and in their anterior portion are intimately related to the vascular and bony structures at the base of the brain. Not surprisingly, localization of lesions within the afferent visual pathways has great value in neurologic diagnosis.

Anatomy of the Visual Pathways

Light entering the eye falls on the retinal rods and cones, which transduce the stimulus into neural impulses to be transmitted to the brain. The distribution of visual function across the retina takes a pattern of concentric zones increasing in sensitivity toward the center, the fovea. The fovea consists of a "rod-free" central grouping of approximately 100,000 slender cones. The ganglion cells subserving these cones send their axons directly to the temporal aspect of the optic disc, where they form the papillomacular bundle. Axons originating from ganglion cells in the temporal retina curve above and below the papillomacular bundle and form dense arcuate bands.

The arteries supplying the optic nerve and retina derive from branches of the ophthalmic artery. The central retinal artery approaches the eye along each optic nerve and pierces the inferior aspect of the dural sheath about 1 cm behind the globe to enter the center of the nerve. The artery emerges in the fundus at the center of the nerve head, from which it nourishes the inner two thirds of the retina by superior and inferior branches. Anastomotic branches derived from the choroidal and posterior ciliary arteries, the ciliary system, supply the choroid, optic nerve head, and outer retinal layers, including the photoreceptors. In about 10% of the population, the macula is supplied by a retinociliary artery, a branch of the ciliary system. Venous drainage from the retina and nerve head flows primarily through the central retinal vein, whose course of exit from the eye parallels that of entry of the artery.

What each eye "sees" is termed its *visual field* (Fig. 432-1). The nasal side of the left retina and the temporal side of the right see the left side of the world, and the upper half of each retina sees the lower half of the world. Behind the eyes, the optic nerves pass through the optic canal to form the optic chiasm. In the chiasm, nerves from the nasal half of each retina decussate and join the fibers from the temporal half of the contralateral retina. From the chiasm, the optic tracts pass around the cerebral peduncles to reach the lateral geniculate ganglia. The orientation of the visual field is rotated 90 degrees in the lateral geniculate such that images from the inferior visual field project to the medial half, whereas images from the superior visual field project to the lateral half. The geniculocalcarine radiation initially fans out into superolateral and inferolateral projections, the latter passing around the lateral ventricle and for a short distance into the temporal lobe (Meyer's loop) before turning posteriorly to reach the striate cortex of the occipital lobe. In the occipital lobe, the striate cortex (area 17) lies along the superior and inferior bands of the calcarine fissure, with macular fibers projecting most posteriorly to the occipital pole and more peripheral retinal projections lying more anteriorly.

Localization of Lesions within Visual Pathways

Monocular vision loss is due to a lesion in one eye or optic nerve. Binocular visual loss, on the other hand, can result from disease located anywhere in the visual pathways from the corneas to the occipital poles. Lesions involving the optic chiasm produce nonhomonymous visual abnormalities (e.g., the bitemporal hemianopia illustrated by lesion 3 in Fig. 432-1). Optic tract abnormalities are comparatively rare but produce characteristic visual changes. The fibers serving identical points in the homonymous half fields do not fully commingle in the optic tract, so lesions damaging this structure produce incongruous homonymous hemianopia. Lesions of the geniculate nuclei, optic radiations, or visual cortex produce congruent hemianopic field defects that may go unrecognized unless the hemianopia intrudes on macular vision. Postgeniculate visual loss can be differentiated from pregeniculate visual loss by (1) a normal funduscopic appearance, (2) intact pupillary light reactions, and (3) appropriate lesions on brain imaging.

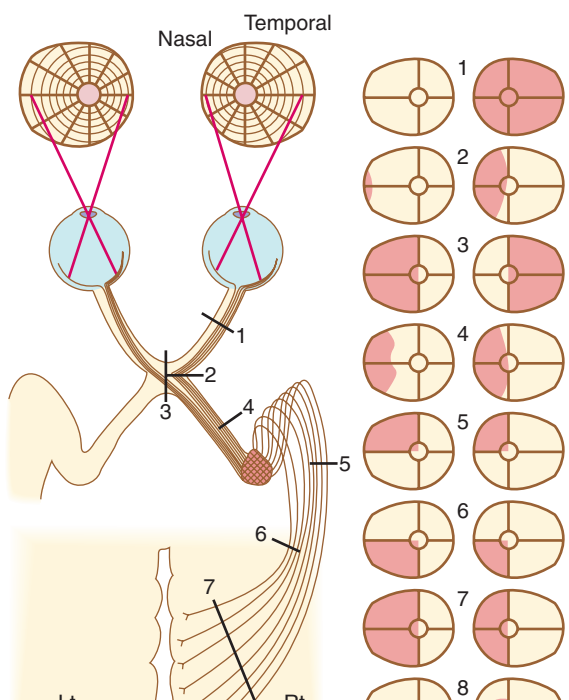

FIGURE 432-1. Visual fields that accompany damage to the visual pathways. *1,* Optic nerve: unilateral amaurosis. *2,* Lateral optic chiasm: grossly incongruous, incomplete (contralateral) homonymous hemianopia. *3,* Central optic chiasm: bitemporal hemianopia. *4,* Optic tract: incongruous, incomplete homonymous hemianopia. *5,* Temporal (Meyer's) loop of the optic radiation: congruous partial or complete (contralateral) homonymous superior quadrantanopia. *6,* Parietal (superior) projection of the optic radiation: congruous partial or complete homonymous inferior quadrantanopia. *7,* Complete parieto-occipital interruption of the optic radiation: complete congruous homonymous hemianopia with psychophysical shift of the foveal point, often sparing central vision and resulting in "macular sparing." *8,* Incomplete damage to the visual cortex: congruous homonymous scotomas, usually encroaching at least acutely on central vision.

Examination of the Afferent Visual System

Visual function is most commonly assessed by "best-corrected visual acuity" (Chapter 431). If visual acuity is not normal, it must be determined whether acuity can be improved with lenses or at least with the use of a pinhole. The normal reference is recognition of letters at an idealized 20 feet, and acuity charts are designed with even larger letters that are normally recognized at proportionally greater distances. Thus, if one reads letters at 20 feet no better than those normally perceived at 40 feet, vision is recorded as 20/40. Small visual charts that are easily carried in the physician's case permit quick and fairly accurate bedside appraisal of acuity.

Visual fields can be tested at the bedside by confrontation, and rough estimates of their integrity can be made even in patients with reduced alertness. The fields should be tested individually for each eye because the pattern of visual field defects can provide important localizing information. A quick screen of the visual fields can be made by having the patient fixate on the examiner's nose and identify the number of fingers flashed in each of the four visual field quadrants. With practice and a cooperative subject, accurate confrontation fields can be obtained that outline even scotomas. Ophthalmoscopic examination permits direct visualization of the retina and optic disc. Corneal, lenticular, or vitreous opacities severe enough to produce visual symptoms can almost always be detected with the ophthalmoscope.

TABLE 432-1 COMMON CAUSES OF TRANSIENT MONOCULAR VISION LOSS

CATEGORY (TYPICAL DURATION)	CAUSES	DIFFERENTIAL FEATURES
Thromboembolism (1-5 min)	Atherosclerosis	Other atherosclerotic vascular disease, associated crossed hemiparesis, angiography (carotid atheroma)
	Cardiac	Valvular disease, mural thrombi, atrial fibrillation, recent myocardial infarction
	Blood dyscrasia	Blood tests positive for sickle cell anemia, macroglobulinemia, multiple myeloma, polycythemia, other
Vasospasm (5-30 min)	Migraine	Ipsilateral headache, other classic aura, family history
Vascular compression (few seconds)	Increased intracranial pressure	Precipitated by position change, Valsalva maneuver, or pressure waves
	Tumor	Associated slowly progressive monocular visual loss
Vasculitis (1-5 min)	Temporal arteritis	Associated headache, polymyalgia rheumatica, palpable temporal artery, elevated sedimentation rate

TABLE 432-2 DIFFERENTIATION OF OPTIC NEURITIS FROM PAPILLEDEMA

	OPTIC NEURITIS	PAPILLEDEMA
Central-cecocentral vision loss	Present	Absent
Distribution	Usually unilateral	Usually bilateral
Ocular pain on movement	Present	Absent
Direct light reflex	±Reduced	Intact
CT and MRI of head	White matter plaques	Tumor, venous occlusion, etc.
Visual evoked responses	Abnormal	Normal
Lumbar puncture pressure	Normal	Elevated

CT = computed tomography; MRI = magnetic resonance imaging.

Common Causes of Visual Loss

Eye

The cause of monocular vision loss secondary to ocular and retinal lesions can often be detected by ophthalmoscopic examination or by measurement of intraocular pressure (Chapter 431). *Glaucoma* caused by impaired absorption of aqueous humor results in a high intraocular pressure that usually produces gradual loss of peripheral vision, "halos" seen around lights, and occasionally, pain and redness in the affected eye. The diagnosis is made by tonometric measurement of high intraocular pressure and may be suspected by palpating an abnormally firm globe and observing a deep, pale optic cup and attenuated blood vessels. *Retinal tears* and *detachments* give rise to unilateral distortions of the visual image seen as sudden angulations or curves of objects containing straight lines (metamorphopsia). *Hemorrhages* into the vitreous humor or *infections* or *inflammatory lesions* of the retina can produce scotomas that resemble those resulting from primary disease of the central visual pathway.

Binocular vision loss secondary to retinal disease in younger subjects is often due to *heredodegenerative conditions.* Vascular diseases, diabetes (Chapter 236), and age-related macular degeneration are causes in older patients. In most cases of *pigmentary retinal degeneration,* visual loss begins peripherally and slowly proceeds centrally. By contrast, *macular degeneration* (see Figs. 431-22 and 431-23 in Chapter 431) impairs central vision early in its course. A common variant in the complement factor H (*CFH*) gene is associated with a markedly increased risk for the development of age-related macular degeneration.

Optic Nerve

Acute or subacute monocular vision loss (Table 432-1) as a result of optic nerve disease is most commonly produced by demyelinating disorders, vascular obstruction, neoplasm, or hereditary optic neuropathy. Demyelinating disease of the nerve head (*optic neuritis* or *papillitis*) produces disc edema along with loss of central vision in the affected eye only; subjectively unrecognized scotomas may sometimes be found in the other eye. Demyelination of the optic nerve behind the point where the retinal vein emerges (*retrobulbar neuritis*) initially leaves a normal-looking disc but a central or paracentral scotoma. With chronic demyelinating disorders, the optic disc becomes pale and atrophic. The clinical course and therapeutic response of optic neuritis depend on the underlying inflammatory mechanism. In more than 50% of patients initially seen with optic neuritis, typical symptoms and signs of multiple sclerosis eventually develop (Chapter 419). Optic neuritis with an associated transverse myelitis is the clinical hallmark of neuromyelitis optica, which is a severe demyelinating disease often mistaken for multiple sclerosis but now recognized to be caused by anti–aquaporin 4 autoantibodies. Intraocular arterial occlusion may produce either central visual loss or an altitudinal field defect (*ischemic optic neuropathy*). *Tumors* (Chapter 195) invading the optic nerve or space-occupying lesions compressing it anywhere between the orbit and chiasm cause gradually decreasing central vision or a sector defect of the peripheral visual field. With such chronic lesions, the affected optic nerve becomes visibly atrophic.

Acute binocular vision loss resulting from bilateral optic nerve disease is most often caused by demyelinating disease or by toxic or nutritional factors (Chapter 425). In younger persons and those lacking a clear history of toxic exposure, demyelinating lesions overwhelmingly predominate. Symptoms are of abrupt or subacute onset with visual blurring, which may progress rapidly to blindness within hours or days. There may be pain about the eyes, particularly with movement. *Leber's optic neuropathy,* caused by a mutation in mitochondrial DNA, typically begins painlessly and centrally in one eye, with the second eye affected weeks to months later.

Papilledema is disc edema secondary to increased intracranial pressure (Table 432-2). Vision is normal except under one of two circumstances: (1) acute transient episodes of amaurosis lasting a few seconds and attributable to acute increases in intracranial pressure (plateau waves) and (2) progressive loss of peripheral vision with long-standing, severe papilledema caused by compression of the optic nerve head. Subacute or chronic binocular vision loss secondary to optic nerve disease can result from *toxic* and *nutritional* causes or from *inherited optic atrophy.* The latter sometimes accompanies spinocerebellar degeneration but may selectively affect the optic nerve. With either cause, visual loss is painless and primarily affects central vision; ophthalmoscopy shows optic atrophy.

Chiasm and Optic Tract

Patients with lesions of the optic chiasm or optic tract are often unaware of visual impairment until the deficit encroaches on central vision in one or both eyes. Intrinsic or extrinsic neoplasms and parachiasmal arterial aneurysms are the most common lesions in this location. Gliomas that arise within the chiasm or optic tract are rare in adulthood. Extrinsic lesions compressing the chiasm or tract include *pituitary adenomas* (Chapter 231), *dysgerminomas, craniopharyngiomas, meningiomas* (Chapter 195), and large *aneurysms* of the carotid or basilar artery (Chapter 415). The diagnosis rests on finding the characteristic visual field abnormalities (bitemporal hemianopia for chiasm and incongruous homonymous hemianopia for optic tract lesions) and identifying the lesion with computed tomography or magnetic resonance imaging. Pituitary apoplexy secondary to acute hemorrhage into the gland (Chapter 231) can result in sudden vision loss; prompt neurosurgical intervention under steroid coverage is required for most patients.

Visual Radiations and Occipital Cortex

Lesions involving the postgeniculate visual pathways most often result from *vascular damage, traumatic injuries, neoplasms,* or rarely, *inflammatory* or *degenerative disorders* involving the cerebral white matter. Their localization can be deduced by the resulting visual field defects. Vascular disease of the occipital lobes is the most common cause of homonymous visual field defects in the middle-aged and elderly population. *Anton's syndrome* refers to cerebral visual loss with denial of a visual defect. Affected patients not only deny that they are blind but also confabulate details of their visual environment from memory. Anton's syndrome results from bilateral lesions involving the

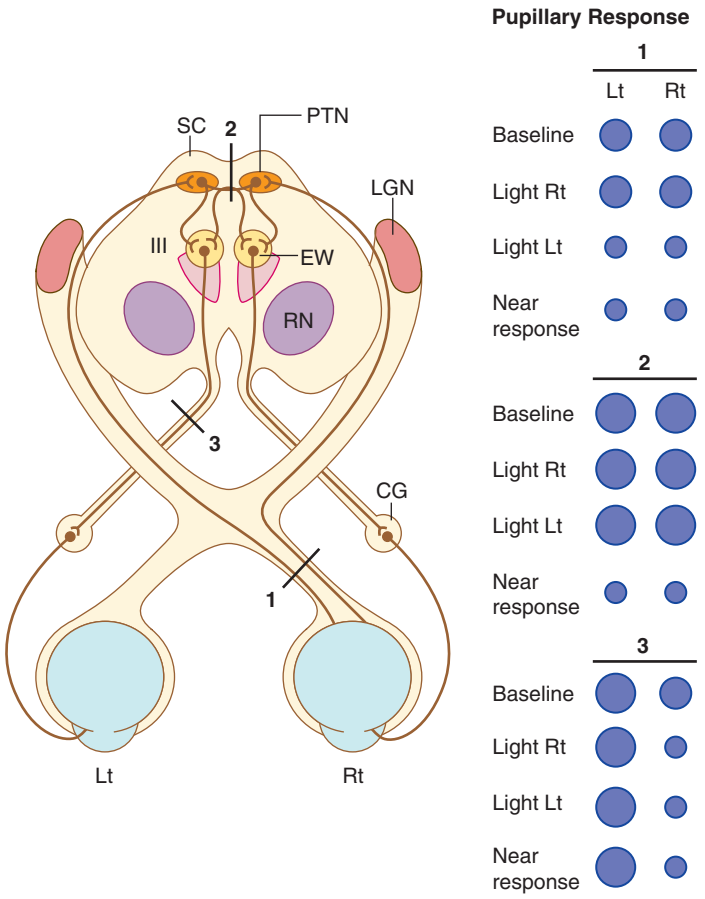

FIGURE 432-2. Pupillary responses associated with lesions of the *(1)* optic nerve, *(2)* pretectum, and *(3)* oculomotor nerve. Baseline is obtained with fixation on a distant target and the near response with a target in front of the nose. CG = ciliary ganglion; EW = Edinger-Westphal nucleus; LGN = lateral geniculate nucleus; PTN = pretectal nucleus; RN = red nucleus; SC = superior colliculus.

parieto-occipital lobes or in the setting of metabolic encephalopathy. The reversible *posterior leukoencephalopathy syndrome,* which is characterized by headache, seizures, confusion, and cortical visual loss, is associated with an abrupt increase in blood pressure, such as may be seen with eclampsia and with immunosuppressive therapy after transplantation.

PUPILLARY CONTROL

The neuromechanisms that control pupil size and reactivity are complex, yet they can be evaluated by simple clinical procedures. The diameter of the pupil is determined by the antagonistic actions of the iris sphincter and dilator muscles, with the latter playing a minor role. If the sphincter muscle is severed or ruptured, it does not retract toward one quadrant but rather continues to function, except in the altered segment. Therefore, pupillary response can be evaluated even in the presence of significant damage to the iris.

Anatomy and Localization of Lesions within Pupillary Pathways

The size of the pupil is governed by tonic balance between sympathetic and parasympathetic innervation of the muscles of the iris. Sympathetic stimulation dilates the pupil, whereas parasympathetic stimulation constricts it. In the normal resting state, light entering the eye provides the major stimulus governing the size of the pupil (Fig. 432-2). Light activates the retinal rods and cones, with maximal sensitivity in the macular area. The optic nerve fibers follow the crossed and uncrossed visual pathways to the pregeniculate portion of the optic tracts, where the receptor fibers for light diverge to the pretectal nucleus located at the midbrain-diencephalic junction. Interneurons project from this nucleus to the Edinger-Westphal nuclei atop the midbrain third nerve nuclear complex of either side. From that point, paired parasympathetic efferents leave the midbrain in the third nerves, travel in the interpeduncular space across the petroclinoid ligament and edge of the tentorium, traverse the cavernous sinus, and then enter the orbit through the superior orbital fissure. In the orbit, the parasympathetic efferents synapse in the ciliary ganglion, from which ciliary nerves enter the eye to reach the pupillary muscles.

FIGURE 432-3. Adie's tonic pupil in the right eye of a young woman. The affected pupil is "tonic"; that is, it responds slowly to light and accommodation but on rapid testing appears unresponsive. The site of the lesion is usually obscure, but the condition is benign. There may be associated areflexia. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

The principal sympathetic control of the pupil originates in the ventral lateral hypothalamus (first-order neuron), from which fibers descend ipsilaterally through the brain stem tegmentum and thence to the cervical cord, where they synapse with preganglionic neurons in the intermedial lateral column of the upper three thoracic segments. Preganglionic fibers (second-order neurons) emerge with the ventral roots of C8, T1, and T2 and ascend in the neck to synapse in the superior cervical ganglion adjacent to the base of the skull. Postganglionic (third-order neurons) pupillary fibers accompany the internal carotid artery through the skull and then leave it to follow the ophthalmic branch of the trigeminal nerve to reach the pupillodilator muscle of the eye.

Examination of the Pupil

The pupillary response to light should be examined in a dimly lighted room, where the pupils are naturally dilated. First, the size and symmetry of the pupils are assessed by shining a dim light onto the face from below so that both pupils are seen simultaneously in the indirect illumination. To test light reactivity, gaze is directed at a distant object (so that constriction secondary to convergence is minimal), and first one and then the other pupil is illuminated with a bright light source. If a pupil reacts poorly to direct light, it is observed as the opposite eye is illuminated (consensual response). Pupils that react poorly to light should be tested for reactivity to the near reflex by first having the patient gaze at a distant object and then quickly fixate on an object just in front of his or her nose. *Light-near dissociation* refers to a pupil that does *not* react to light but does accommodate by constricting to a near target.

Common Causes of Pupillary Abnormalities

With so-called benign pupillary dilation or *physiologic anisocoria,* there is a long-standing difference in the size of the two pupils with normal reflex reactions; the disparity remains constant during constriction and dilation. Lesions compressing or damaging the pretectal region interrupt the afferent light reflex bilaterally to produce dilated and light-fixed pupils (e.g., lesion 2; see Fig. 432-2). Pupillary constriction to the near response is preserved until late stages. Tumors of the pineal gland (e.g., dysgerminomas) and *localized infarctions* are the most common lesions in this location. *Adie's tonic pupil* (Fig. 432-3) is a medium to large (3 to 6 mm) pupil that constricts little or not at all to light and very slowly to accommodation but constricts with the instillation of dilute (0.125%) pilocarpine (Fig. 432-4). The condition usually affects one eye (occasionally both), is more common in women 25 to 45 years of age, and carries no serious implications. It most likely results from postviral denervation of the pupillary muscles. Unexplained unilateral or bilateral dilated pupils as an isolated finding can result from *accidental or intentional instillation of mydriatic drugs.* Transdermal scopolamine is a common cause. Failure of the pupil to constrict promptly with pilocarpine (1%) gives the diagnosis if the history is unclear. Interruption of the emerging third nerve in the ventral midbrain or along the proximal part of its course produces a dilated pupil 6 to 7 mm in diameter. Important causes of compression of the third nerve in this region are *aneurysms* (Chapter 415), *neoplasia* (Chapter 195), and *brain herniation* (Chapter 195) as a result of increased intracranial pressure. In nearly all cases, the pupillary involvement is associated with other signs of third nerve involvement (see later text).

Sympathetic paralysis of the eye with ptosis, anhidrosis, and miosis (Horner's syndrome; Fig. 432-5) can result from lesions anywhere along the pathway of the sympathetic innervation to the eye (Table 432-3). The diagnosis can sometimes be made by identifying associated signs in the brain

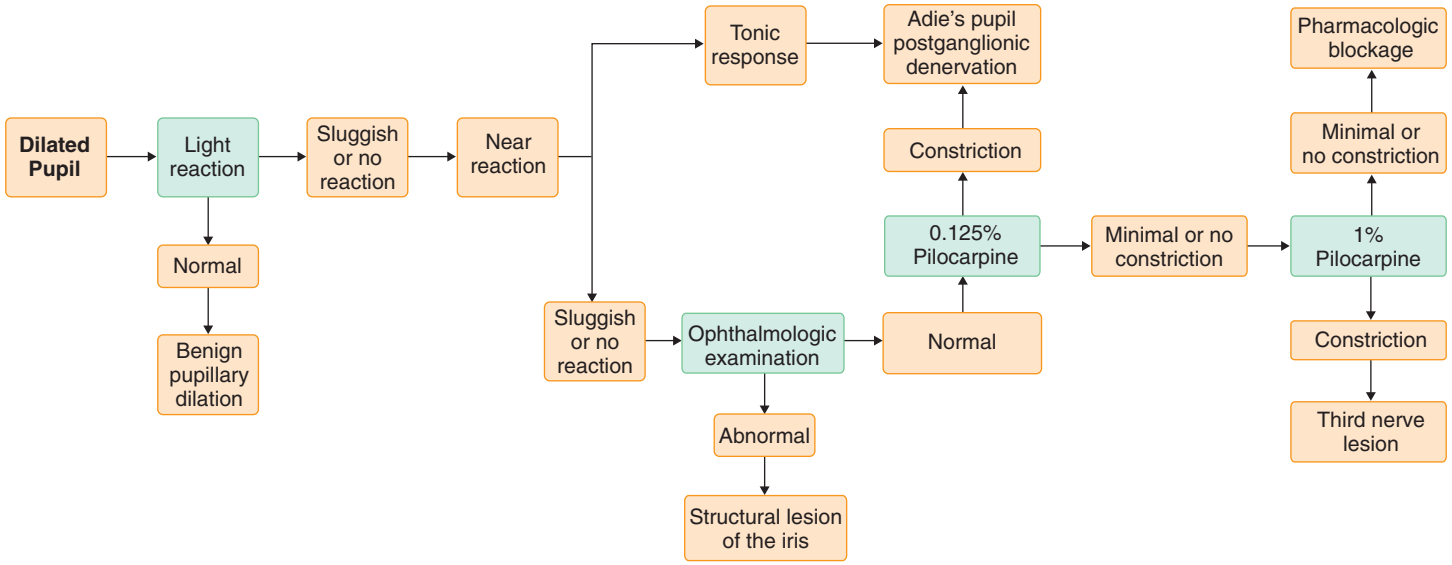

FIGURE 432-4. Use of pilocarpine to help differentiate between different causes of a dilated pupil.

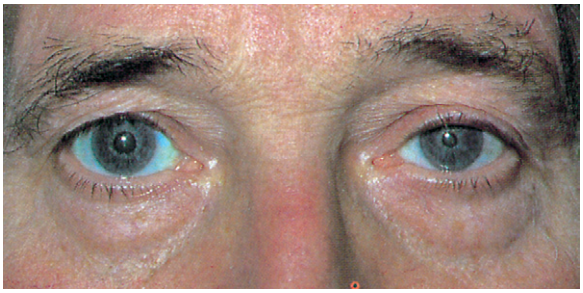

FIGURE 432-5. Horner's syndrome. Note the characteristic ptosis of the left eye associated with constriction of the pupil (miosis). This patient had syringomyelia, but Horner's syndrome has many possible causes. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

TABLE 432-3 HORNER'S SYNDROME RESULTS FROM LESIONS IN MULTIPLE LOCATIONS

LOCATION OF LESION	NEURON INVOLVED	TYPE OF LESION	ASSOCIATED SYMPTOMS AND SIGNS
Lateral brain stem	1st order	Infarction, glioma	Vertigo, nystagmus, imbalance, numbness, weakness
Apex of lung	2nd order	Lung cancer, trauma	Often none
Neck	3rd order	Carotid dissection or inflammation	Pain, monocular visual loss, hemiparesis

stem or neck or along the carotid artery. *Argyll Robertson pupils* are small (1 to 2 mm), unequal, irregular, and fixed to light; they constrict minimally to accommodation. Their principal cause is tertiary neurosyphilis (Chapter 327).

OCULOMOTOR CONTROL

Abnormal eye movements can result from disturbances at several levels. Disconjugate eye movements result from lesions in the individual ocular muscles, the myoneural junctions, the oculomotor nerves and their three paired nuclei in the brain stem, and the internuclear medial longitudinal fasciculus (MLF), which yokes the eyes in horizontal movements. Supranuclear lesions typically produce disorders of conjugate gaze (gaze palsies).

Anatomy and Localization of Lesions within the Oculomotor Pathways

Nuclear and Internuclear Pathways

The abducens (sixth) nerve supplies the lateral rectus muscle. Selective involvement of the abducens nerve anywhere along its pathway leads to isolated weakness of abduction of the affected eye. Destruction of the abducens nucleus in the brain stem results in a conjugate gaze paralysis (ipsilateral) because, in addition to oculomotor neurons, the nucleus contains interneurons destined for the contralateral medial rectus nucleus. The trochlear (fourth) nerve supplies the contralateral superior oblique muscle, which turns in and depresses the eye. Patients with superior oblique weakness note an increase in diplopia with head tilt toward the side of weakness and often tilt their head in the opposite direction. At rest, there is slight upward deviation of the involved eye, and downward movement is impaired when the affected eye is turned in. Patients typically complain of diplopia when reading or going down stairs. The third (oculomotor) cranial nerve supplies the remaining ocular muscles. Involvement of the third nerve nucleus in the midbrain always produces at least some bilateral oculomotor weakness; the superior rectus division of the nucleus supplies the contralateral superior rectus muscle (all other divisions supply ipsilateral muscles). Peripheral third nerve paralysis can result from lesions damaging the structure anywhere from its course within the ventral midbrain to where it enters the orbit through the superior orbital fissure. When complete, third nerve palsy produces a widely dilated pupil, severe ptosis, and an externally deviated eye held in position by unopposed contraction of the lateral rectus muscle. In such conditions, the continued trochlear action reveals itself by intorsion of the eye when the subject attempts to look down.

The MLF interconnects the abducens nucleus in the pons with the contralateral oculomotor nuclear complex in the midbrain. It terminates cephalad in the interstitial nucleus in the rostral midbrain and can be traced as far caudad as the thoracocervical region of the spinal cord (coordinating nuchal-ocular control). Lesions involving the MLF characteristically produce internuclear ophthalmoplegia (INO), in which the eyes are conjugate in the primary position but disconjugate on lateral gaze. With fully developed INO on lateral gaze away from the side of the lesion, the contralateral eye abducts and shows nystagmus, whereas the ipsilateral adducting eye does not move nasally because of failure of ascending impulses to reach the medial rectus division of the third nerve nucleus. Adduction for convergence is usually relatively maintained.

Supranuclear Pathways

Pathways descending from the frontal eye fields in the frontal lobe through the superior colliculi to the contralateral brain stem regulate rapid voluntary eye movements (*saccades*) (Table 432-4). Pathways descending from the parieto-occipital and frontal regions to the ipsilateral brain stem subserve slow visual tracking (smooth pursuit—foveal target; optokinetic—full-field target). For the vestibulo-ocular reflex, primary afferent neurons in the inner ear synapse with neurons in the vestibular nuclei, which in turn synapse with appropriate oculomotor neurons to produce compensatory eye movements. The *convergence* center is located in the rostral-dorsal midbrain near the vertical gaze center.

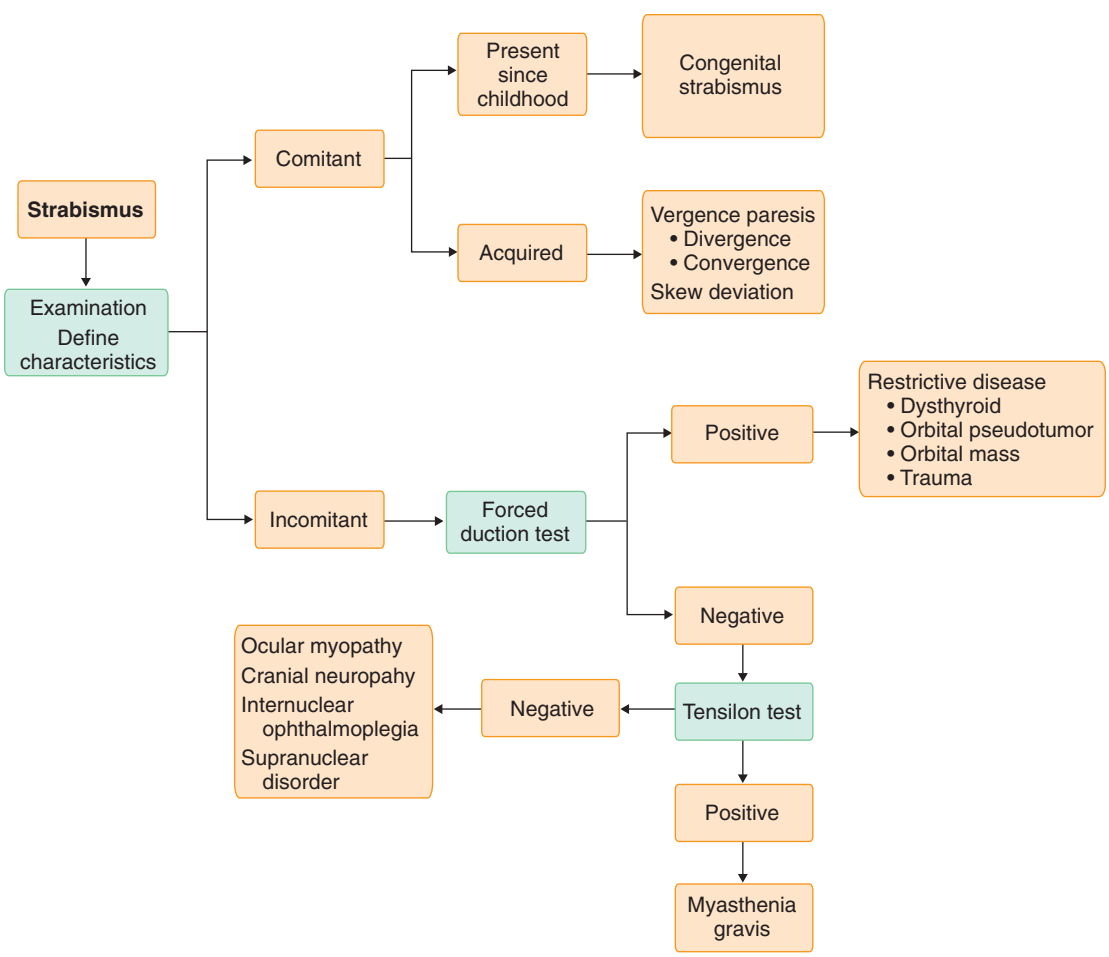

FIGURE 432-6. Diagnostic tests that help differentiate among common causes of strabismus.

TABLE 432-4 SUPRANUCLEAR OCULOMOTOR CONTROL SYSTEMS

SYSTEM	DESCRIPTION	FUNCTION	KEY ANATOMIC STRUCTURES
Saccade	Fast conjugate voluntary movements	Move the fovea to a new target of interest	Frontal eye field, superior colliculus, pretectum—vertical, pontine—horizontal cerebellar dentate nucleus
Smooth pursuit/ optokinetic	Slow conjugate tracking	Match eye velocity to target velocity	Occipital, parietal, pons, cerebellar flocculus
Vestibulo-ocular	Slow conjugate compensatory eye movements	Keep eyes stable when head moves	Pontomedullary region
Vergence	Slow disconjugate tracking	Focus on near and far targets	Pretectum, tectum

TABLE 432-5 KEY DISTINGUISHING FEATURES OF PERIPHERAL AND CENTRAL TYPES OF SPONTANEOUS AND POSITIONAL NYSTAGMUS

TYPE OF NYSTAGMUS	PERIPHERAL (END ORGAN AND NERVE)	CENTRAL (BRAIN STEM AND CEREBELLUM)
Spontaneous	Unidirectional, fast phase away from the lesion, combined horizontal torsional, inhibited with fixation	Bidirectional or unidirectional; often pure horizontal, vertical, or torsional; *not* inhibited with fixation
Static positional	Fixed or changing direction, inhibited with fixation	Fixed or changing direction, *not* inhibited with fixation
Paroxysmal positional	Vertical-torsional, occasionally horizontal-torsional, vertigo prominent, fatigability, latency	Often pure vertical, vertigo less prominent, no latency, nonfatigable

Examination of Eye Movements

Fixation and gaze holding are tested by having the patient look center, right, left, up, and down. Each position should be held steady and unwavering with the observer carefully documenting abnormal movements or ocular disconjugacies. Each supranuclear oculomotor control system is examined separately. *Saccades* are tested by having the patient alternately fixate on two targets such as the examiner's finger and nose; the speed and accuracy are noted. *Smooth pursuit* is tested by slowly moving a target back and forth and up and down and observing the patient's ability to produce smooth tracking movements. If the target velocity is low, normal subjects should be able to pursue without requiring catch-up saccades. The *vestibulo-ocular reflex* is evaluated with the head-thrust test (Chapter 436). *Convergence* is tested by having the patient follow a target moving from far to near. The degree of convergence depends to some extent on the cooperation of the patient. A clear sign that the patient is attempting to converge is simultaneous pupillary constriction.

Common Causes of Abnormal Oculomotor Control

Strabismus (Ocular Misalignment)

A comitant (same in all directions of gaze) strabismus present since childhood is usually a benign *congenital disorder.* Latent congenital strabismus can become manifested in adulthood in association with a systemic illness. An acquired skew deviation (vertical displacement of the ocular axes) indicates a lesion within the otolith-ocular pathways (generally the brain stem). Incomitant strabismus can result from restrictive disease of the orbit or from abnormal muscle or oculomotor nerve function. The presence of mechanical restriction is confirmed by the use of forced duction testing (Fig. 432-6) (After a topical anesthetic is applied to the eye, the ophthalmologist grasps

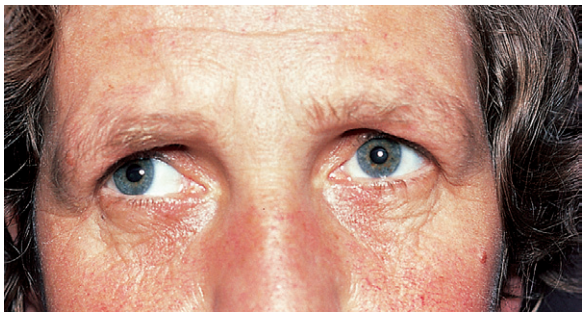

FIGURE 432-7. Internuclear ophthalmoplegia may be an initial feature of brain stem involvement in multiple sclerosis. On lateral gaze to the right, adduction of the left eye is incomplete. On convergence, eye movement was normal. The lesion is in the left medial longitudinal bundle, between the nucleus in the pons and the third nerve nucleus on the opposite side. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

the muscle insertion with large blunt-toothed forceps. Failure of the eye to deviate fully in the pulled direction implies restriction.) Common causes of *orbital restrictive disease* include dysthyroid ophthalmopathy (Chapter 233), orbital pseudotumor, trauma, and orbital mass lesions (Chapter 431). Variable strabismus that increases with fatigue suggests *myasthenia gravis* (Chapter 430). A Tensilon test can usually confirm the diagnosis (see Fig. 432-6). If both restrictive disease and myasthenia gravis (Chapter 430) have been excluded, most patients with incomitant strabismus have processes affecting the oculomotor nuclei, their fascicles, or the cranial nerves themselves. Common causes of an *isolated third nerve palsy* in an adult include aneurysm (Chapter 413), small-vessel occlusive disease (including diabetes mellitus (Chapter 236), trauma (Chapter 406), and neoplasm. Typically, third nerve lesions secondary to vascular disease spare the pupil. Vascular disease and trauma are by far the most common causes of *isolated trochlear nerve palsy.* The abducens nerve is particularly vulnerable to isolated traumatic involvement because of its long pathway outside the brain stem. Lesions that produce increased intracranial pressure (Chapter 195) can lead to abducens nerve dysfunction regardless of the location and produce a "false localizing sign." Other common causes of *isolated sixth nerve palsy* are vascular disease (Chapter 414), trauma (Chapter 406), and neoplasm. About one fourth of cases of cranial nerve palsy (third, fourth, or sixth nerves) remain undiagnosed.

Internuclear Ophthalmoplegia

INO (Fig. 432-7) may be unilateral or bilateral, partial or complete, depending on the location of the lesion and the degree of damage to the MLF. *Demyelinating* and small *vascular lesions* are the most common causes of unilateral INO unaccompanied by other ocular palsies or brain stem signs. Larger brain stem lesions that damage one or more oculomotor nuclei plus the MLF often produce combinations of disconjugate eye movements coupled with nuclear oculomotor palsies. Myasthenia gravis (Chapter 430) can produce an ophthalmoparesis resembling INO as a result of greater involvement of the medial rectus than the lateral rectus. Demyelinating diseases (Chapter 419) are the most common causes of bilateral INO involvement.

Disorders of Conjugate Gaze

Acute lesions involving a frontal eye field (e.g., hemorrhage or infarction [Chapters 414 and 415]) result in a transient inability to direct the eyes contralaterally. Vertical eye movements are not affected by unilateral lesions. Bilateral damage to the frontal eye fields or their descending pathways may produce an inability to move the eyes voluntarily (horizontal or vertical) despite preserved reflex eye movements, a condition called *oculomotor apraxia.* Lesions involving the horizontal gaze center in the pons produce an ipsilateral paralysis of conjugate gaze and tonic deviation of the eyes to the contralateral side (Chapter 431). Lesions of the pretectum selectively impair vertical gaze, with the vertical upgaze center being slightly rostral and dorsal to the vertical downgaze center. Patients with the *dorsal midbrain syndrome* (Parinaud's syndrome) have a conjugate upgaze paresis. When they attempt to make upward saccades, convergence retraction nystagmus develops. As noted earlier, impaired convergence and light-near dissociation of the pupillary reflexes are also part of the syndrome. The most common causes of the dorsal midbrain syndrome include tumors of the pineal gland (Chapter 230) (dysgerminomas), hydrocephalus (Chapter 195), and localized infarction. With the so-called locked-in syndrome (secondary to basilar artery thrombosis [Chapter 411]), voluntary horizontal eye movements are absent; the patient's only remaining motor functions are vertical eye and lid movements.

Nystagmus

Spontaneous nystagmus can be congenital or acquired. *Congenital nystagmus* typically has a high frequency and variable waveform (usually pendular) and is highly fixation dependent. It generally remains horizontal in all positions of gaze. The lifelong history and lack of symptoms confirm the diagnosis. Spontaneous nystagmus resulting from a *peripheral vestibular* lesion (i.e., in the labyrinth or vestibular nerve) usually has combined horizontal and torsional components (Table 432-5). The nystagmus resolves within a few days of the acute lesion. Acquired persistent spontaneous nystagmus indicates a lesion in the brain stem or cerebellum, or both. The latter is often purely vertical, horizontal, or torsional. Spontaneous *downbeat nystagmus* is commonly seen with lesions of the cerebellum or cervicomedullary junction (e.g., Arnold-Chiari malformation [Chapter 426]).

Gaze-evoked nystagmus is always in the direction of gaze and is usually present with and without fixation. It is most commonly produced by the ingestion of *drugs* such as phenobarbital, phenytoin, alcohol, and diazepam (Chapter 110). It can also occur in patients with such varied conditions as myasthenia gravis (Chapter 430), multiple sclerosis (Chapter 419), and cerebellar atrophy. Asymmetrical horizontal gaze-evoked nystagmus is caused by a structural brain stem or cerebellar lesion (particularly at the cerebellopontine angle), with the lesion generally being on the side of the larger-amplitude nystagmus (Bruns' nystagmus). *Rebound nystagmus* is a type of gaze-evoked nystagmus that either disappears or reverses direction as the eccentric gaze position is held. When the eyes are returned to the primary position, nystagmus occurs in the direction of the return saccade. Rebound nystagmus occurs in patients with cerebellar atrophy and focal structural lesions of the cerebellum; it is the only variety of nystagmus thought to be specific for cerebellar involvement. *Disconjugate gaze–evoked nystagmus* most commonly results from lesions of the MLF (see earlier discussion), but it can also occur with other lesions of the brain stem involving the oculomotor nuclei. Positional nystagmus is discussed in Chapter 436.

Other Ocular Oscillations

Ocular bobbing consists of a fast conjugate downward eye movement followed by a slow return to the primary position. The phenomenon accompanies severe displacement or destruction of the pons or, less often, metabolic central nervous system depression. *Ocular myoclonus* consists of continuous rhythmic pendular oscillations, most often vertical, at a rate of 1 to 3 beats per second; it often accompanies palatal myoclonus and has a similar pathogenesis. *Square-wave jerks* and *ocular flutter* consist of brief, intermittent, horizontal oscillations (back to back saccades) arising from the primary gaze position. These types of ocular oscillation are most commonly seen with cerebellar disease but can also accompany more diffuse central nervous system disorders. *Opsoclonus* consists of rapid, chaotic, conjugate, repetitive saccadic eye movements (dancing eyes). Opsoclonus accompanies the cerebellar dysfunction, with the most chaotic varieties associated with brain stem encephalitis or the remote effects of systemic neoplasm, especially neuroblastoma in children. *Ocular dysmetria* refers to overshooting and undershooting of saccadic eye movements, often followed by multiple attempts at refixation. It reflects cerebellar dysfunction.

DISEASES OF THE MOUTH AND SALIVARY GLANDS

TROY E. DANIELS

More than 200 primary lesions or diseases occur in the oral mucosa, gingiva, teeth, jaws, and minor or major salivary glands. In addition, secondary abnormalities of the oral mucosa or salivary glands can be caused by systemic diseases or drugs. The most common or important of these diseases may be observed during physical examination and are often part of a systemic process.

ORAL MUCOSAL DISEASES

Acute Ulcerations

Painful short-term ulcerations are caused by mechanical trauma, immunologic mechanisms, or bacterial or viral infections (Table 433-1). Soon after formation, oral mucosal ulcers become covered by a white to gray pseudomembrane, analogous to scabs on dry epidermis. Pseudomembrane-covered ulcers are distinguished from white hyperkeratotic lesions by their clinical features of pain, a flat surface, and an erythematous periphery. Traumatic ulcers are characteristically located on the tongue or inside the cheeks or lips, are close to the chewing surfaces of the teeth, and have irregular borders.

APHTHOUS STOMATITIS ("CANKER SORES")

These idiopathic recurrent ulcers, which afflict up to 20% of the population, are found on all areas of the oral mucosa except the hard palate, gingiva, and vermilion, which are keratinized (Fig. 433-1). They form well-defined circular lesions that may be single or multiple. There are three clinical forms: (1) minor, which are flat and less than 1 cm in diameter and last 5 to 10 days; (2) major, which have raised borders, are greater than 1 cm, and often last for weeks or months; and (3) herpetiform, which are usually clusters of very small ulcers that resemble recurrent herpetic lesions but are not preceded by vesicles and do not occur on keratinized mucosa. A viral pathogenesis has not been established for any of these forms. Lesions clinically identical to minor aphthae occur in Behçet's syndrome (Chapter 278). Aphthae are occasionally associated with anemias or gluten-sensitive enteropathy and may become more frequent and severe in association with human immunodeficiency virus (HIV) infection (Table 433-2).

Minor or herpetiform aphthous ulcers may not require treatment unless they occur frequently.■ Topical steroids, such as fluocinonide gel or ointment, can reduce the severity and duration of the lesions only if applied with prodromal symptoms or earliest signs. Major aphthae usually require treatment with prednisone (e.g., 40 mg daily for 3 days); failure to respond significantly should prompt incisional biopsy to exclude neoplasia.

VIRAL ULCERS

Several types of virus (most commonly herpes simplex type 1; Chapter 382) cause multiple oral mucosal vesicles that last only a few hours or days and then become irregular shallow ulcers. In the initial infection by herpes simplex virus, usually in children, numerous vesicles may appear on any oral mucosal site (primary herpetic gingivostomatitis), accompanied by malaise, headache, fever, and cervical lymphadenopathy. Patients previously exposed to this virus may develop recurrent (secondary) lesions as clusters of small vesicles, most commonly on the lips (herpes labialis) and less commonly on the keratinized mucosa of the gingiva or hard palate (Fig. 433-2). Such lesions contain live virus and tend to recur at the same site but less frequently with increasing age.

Similar mucosal vesicles may also accompany the initial infection by the varicella-zoster virus in children with chickenpox (Chapter 383), and unilateral lesions may occur if herpes zoster (Chapter 383) affects branches of the trigeminal nerve. Uncommonly, oral mucosal ulcers may be caused by different types of coxsackievirus (Chapter 387), appearing on any oral site in hand-foot-and-mouth disease or on the soft palate or pharynx in herpangina. After infection by the measles (rubeola) virus, small ulcers (Koplik's spots) may form on the inside of the cheeks 1 to 2 days before development of the skin rash (Chapter 375).

TABLE 433-1 ORAL MUCOSAL ULCERS

TYPE/DISEASE	CLINICAL FEATURES
Insidious Onset, Chronic	
Multiple or bilateral	Shallow ulcers on mucosa, skin, or both
Pemphigus vulgaris	Begin as short-duration blisters
Mucous membrane pemphigoid	Begin as short-duration blisters
Lichen planus	Bilaterally symmetrical lesions (associated with hyperkeratosis and/or erythema)
Lupus erythematosus	Asymmetrical lesions, with or without systemic lupus (associated with hyperkeratoses and/or erythema)
Drug reaction	Variable lesions; appropriate history of drug use (e.g., penicillamine, gold)
Epidermolysis bullosa	Begin as blisters; lifelong history
Solitary	Indurated or cratered ulcers
Squamous cell carcinoma	Most common on tongue, oropharynx, lip, mouth floor
Adenocarcinomas, various	Most commonly on palate, cheeks, mouth floor
Tuberculosis	Usually painful
Actinomycosis	Often associated with draining sinus
Deep mycoses (particularly histoplasmosis, coccidioidomycosis)	Associated with systemic infection
Midline granuloma	Associated with necrosis, may perforate palate
Underlying osteonecrosis	Associated with prior cancer radiation therapy or bisphosphonate use
Acute Onset, Often Self-Limiting	
Clusters	Usually small and shallow ulcers; history of blisters
Primary herpes simplex	Any oral mucosal site, associated with fever, malaise
Recurrent herpes simplex	Only on gingiva, hard palate, or lip (keratinized mucosa)
Varicella-zoster	Unilateral lesions along neural distribution
Herpangina	Usually on oropharynx
Measles (rubeola)	Precede skin rash; associated with fever, malaise
Solitary or multiple (without clustering)	Variable, usually without history of blisters
Traumatic ulcers	Usually solitary; history of trauma
Aphthous stomatitis (canker sores)	Circular, often multiple, only on nonkeratinized mucosa
Behçet's syndrome	Oral lesions similar to recurrent aphthae
Erythema multiforme	Multiple lesions, often involve lower labial mucosa; can be recurrent or chronic
Drug reaction	Appropriate history of drug use
Necrotizing sialometaplasia	Deep ulcers, usually on palate
Primary syphilis	Solitary, indurated, painless, any site
Gonorrhea	Painful, surrounded by erythema, any site

ERYTHEMA MULTIFORME

In this potentially recurrent disease, painful oral mucosal ulcerations develop rapidly, with or without target-like skin lesions. It may be associated with a previous viral infection or hypersensitivity to a food or drug. The affected patients, usually young adults with minimal or no systemic symptoms, have irregularly shaped ulcers that can be small and few or involve large areas of the mucosa; the most common sites are the lower labial mucosa and vermilion. These lesions can be distinguished from those of primary herpes by the absence of oral vesicles and systemic symptoms or by the presence of characteristic skin lesions (Chapter 447). A major variant of this disease is Stevens-Johnson syndrome, in which ocular, genital, and other lesions may accompany the oral lesions.

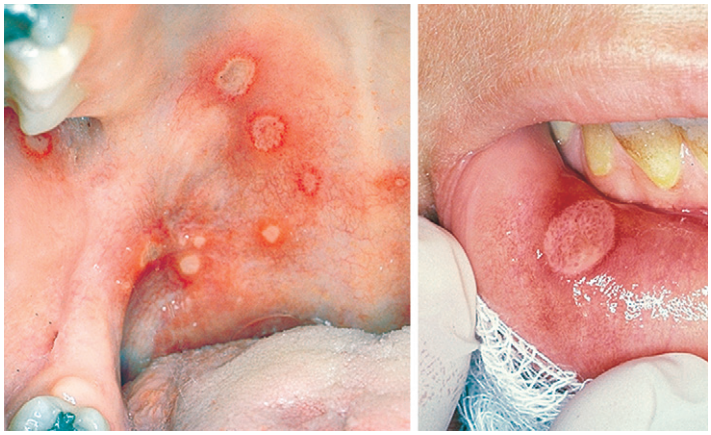

FIGURE 433-1. Aphthous ulcers. *Left,* A cluster of minor aphthae on the soft palate and buccal mucosa, present about 1 week. *Right,* A major aphthous ulcer on the labial mucosa, present about 3 weeks.

FIGURE 433-2. Clusters of recurrent herpes simplex vesicles. *Left,* on the lip; *right,* on the hard palate, both present 2 to 3 days, in different patients.

TABLE 433-2 ORAL LESIONS ASSOCIATED WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Kaposi's sarcoma (human herpesvirus type 8)
Candidiasis Pseudomembranous lesions Hyperplastic lesions Erythematous lesions
Other opportunistic fungal infections (e.g., histoplasmosis or coccidioidomycosis)
Aphthous ulcers (increased frequency, duration, or size)
Virus-associated epithelial hyperplasias Hairy leukoplakia (Epstein-Barr virus) Oral wart (human papillomavirus type 11 and other types) Focal epithelial hyperplasia (Heck's disease) (human papillomavirus types 13 and 32) Condyloma acuminatum (human papillomavirus types 6 and 11)
Herpes zoster (varicella-zoster virus)
Exaggerated forms of gingivitis and inflammatory periodontal disease
Decreased salivary gland function
Parotid gland enlargement (lymphoepithelial lesion)
Non-Hodgkin's lymphoma

VENEREAL INFECTIONS

Primary syphilis may arise as a solitary, indurated, painless ulcer on the oral mucosa that resolves spontaneously in 4 to 6 weeks (Chapter 327). Uncommonly, *Neisseria gonorrhoeae* may cause oral ulcers, usually in the pharynx, which may be confused with oral ulcers of other causes.

Oral Squamous Cell Carcinoma

About 4% of all cancers occur in the mouth, commonly as squamous cell carcinomas of the mucosal epithelium (Chapter 196). Oral carcinoma occurs usually in the fifth decade or beyond, in men twice as frequently as in women, and is associated with long-term use of tobacco in more than 80% of cases.

FIGURE 433-3. Squamous cell carcinoma. Biopsy of this area of erythroplakia with slight induration in the anterior mouth floor exhibited squamous cell carcinoma.

TABLE 433-3 WHITE AND RED/BLUE ORAL MUCOSAL LESIONS

WHITE LESIONS (PLAQUES)
Squamous cell carcinoma (early)
Frictional keratosis (buccal mucosa at dental occlusal line)
Leukoplakia (with or without dysplasia)
Smokeless tobacco–associated lesions
Nicotine stomatitis (palate)
Lichen planus (reticular and plaque types)
Pseudomembranous candidiasis (thrush)
Hyperplastic candidiasis (candidal leukoplakia)
Hairy leukoplakia (HIV associated; usually on lateral tongue)
Geographic tongue
Mucous patch or condyloma latum of secondary syphilis
Pseudomembrane-covered ulcers (see Table 433-1)
RED OR BLUE LESIONS (MACULAR, MACULOPAPULAR)
Squamous cell carcinoma (early)
Erythroplakia (epithelial dysplasia)
Erythematous (atrophic) candidiasis
Median rhomboid glossitis
Mucocutaneous diseases (see Table 433-1)
Angular cheilitis
Telangiectasias and purpuras (red to blue)
Kaposi's sarcoma (blue to purple)

HIV = human immunodeficiency virus.

Oral carcinoma usually arises as a chronic, indurated, cratered ulcer, but white (leukoplakia) and especially red (erythroplakia) macular lesions (Table 433-3; Fig. 433-3) frequently exhibit premalignant dysplasia or early carcinoma. Oral carcinomas spread to cervical lymph nodes. The overall 5-year survival rate is about 50%, but early treatment of small, localized lesions can lead to survival rates as high as 90%.

Other Chronic Ulcerations

Prescription drugs that can be responsible for chronic oral mucosal ulcerations include barbiturates, β-blockers, nonsteroidal anti-inflammatory drugs, and many others (see *http://emedicine.medscape.com/article/1080772-overview*). Several mucocutaneous diseases can cause chronic multifocal oral mucosal lesions composed of ill-defined areas of erythema and ulceration. They are among the most difficult oral lesions to diagnose and are discussed later with the red lesions (see Table 433-3). Several microbial infections or underlying osteonecrosis (e.g., associated with bisphosphonate use) can lead to indurated, chronic oral mucosal ulcerations with moderate symptoms (see Table 433-1).

White Lesions

White plaques are commonly found in the mouth but, like ulcerations, have a wide variety of causes and outcomes (see Table 433-3). The term *leukoplakia* applies to a white plaque that does not rub off and whose appearance does not indicate another disease. Leukoplakia can occur in any area of the mouth and usually exhibits benign hyperkeratosis on biopsy (see Fig. 196-1

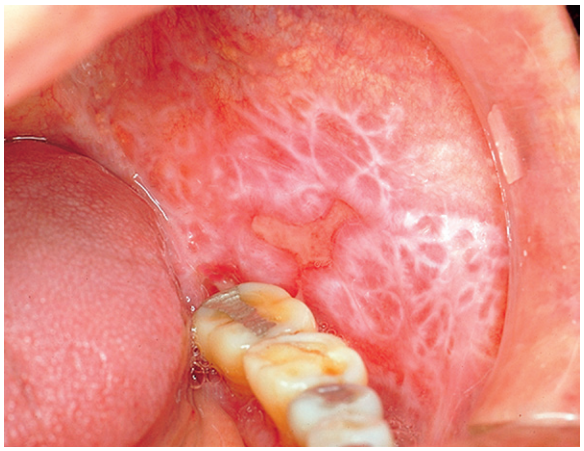

FIGURE 433-4. Lichen planus. A similar-appearing lesion is also present on the right buccal mucosa. Note central pseudomembrane-covered ulceration.

FIGURE 433-5. Hairy leukoplakia. These white plaques were the first visible sign of human immunodeficiency virus infection.

in Chapter 196). On long-term follow-up, 2 to 6% of these lesions undergo malignant transformation into squamous cell carcinoma. Areas of leukoplakia with a corrugated surface or mixed with areas of erythema are often found in the lower labial or buccal vestibule of patients who use smokeless tobacco.

Frictional keratoses are often found posterior to the lower molar teeth as irregular white plaques and on the buccal mucosa as white lines adjacent to the dental occlusion. Unlike leukoplakia, these lesions rarely become malignant.

LICHEN PLANUS

Oral lesions of lichen planus (Chapter 446) occur in about 1% of the population, usually as multiple, bilaterally symmetrical reticular white plaques, with or without adjacent areas of erythema (atrophy or erosion) or irregular ulcers (Fig. 433-4). The presence of mucosal atrophy, erosion, or ulceration usually causes pain and sensitivity to certain foods. Most lesions can be adequately controlled by topical application of fluocinonide or clobetasol gel or ointment (0.05%, three times a day) for periods of several weeks to several months, although recurrence is common.

ORAL CANDIDIASIS

This common fungal disease (Chapter 346) has three clinical forms: pseudomembranous (thrush), erythematous (atrophic), and hyperplastic (candidal leukoplakia). Pseudomembranous candidiasis, usually of relatively short duration, occurs on any site and consists of white fungal plaques that can be rubbed off, leaving a red or bleeding base. Lesions of hyperplastic candidiasis are white, have fungal hyphae within the surface layers of hyperkeratotic epithelium, do not rub off, and are most often found on the anterior buccal mucosa or on the tongue. Erythematous candidiasis is discussed under Red Lesions. All forms of oral candidiasis represent overgrowth or superficial infection by *Candida* species from the oral flora, induced by a variety of causes, including suppression of bacterial flora by systemic antibiotics, chronic salivary dysfunction, uncontrolled diabetes mellitus or anemia, and immunosuppression (especially in HIV-infected patients).

HAIRY LEUKOPLAKIA

The lesion of hairy leukoplakia, which is caused by Epstein-Barr virus, is a white plaque occurring most frequently on the lateral surfaces of the tongue bilaterally in immunosuppressed persons, usually HIV infected (Fig. 433-5). *Candida* may be present in the surface layers, but the lesion is not eliminated by effective antifungal therapy. The diagnosis of hairy leukoplakia by biopsy should raise suspicion of HIV infection or other forms of immunodeficiency.

GEOGRAPHIC TONGUE

Also called *benign migratory glossitis,* this benign idiopathic condition affects the dorsal tongue of about 2% of the population. It is characterized by well-defined areas of atrophied filiform papillae bordered by arcs of normal or hyperplastic filiform papillae and by gradual changes in the location of these lesions over time (Fig. 433-6). Treatment is usually not necessary.

FIGURE 433-6. Geographic tongue. The distribution of these changes on the dorsal tongue may change over time, but they are asymptomatic and diagnosed by their characteristic appearance.

SECONDARY SYPHILIS

Secondary syphilis may manifest as a well-defined white plaque on the labial or palatal mucosa, called *condyloma latum* (or "split papule," because of its lobulated periphery), or as a mucous patch.

Red Lesions

Solitary red macules or plaques (*erythroplakia*) are less common in the mouth than white lesions but should be viewed with concern because they may exhibit premalignant dysplasia, carcinoma in situ, or carcinoma (see Table 433-3 and Fig. 433-3). One exception is a red macule occurring in the midline of the posterior dorsal tongue, classified as *median rhomboid glossitis*, which is an idiopathic but uniformly benign condition that is often associated with localized overgrowth of *Candida* species.

ERYTHEMATOUS (ATROPHIC) ORAL CANDIDIASIS

This chronic condition is characterized by erythema and atrophy of the filiform papillae on the dorsal tongue or by patchy, ill-defined erythema on the palate, tongue, or buccal mucosa (Fig. 433-7). It is usually accompanied by symptoms of oral mucosal burning and sensitivity to spicy foods. It occurs most commonly in patients with chronic salivary hypofunction (e.g., Sjögren's syndrome or anticholinergic drug effects), but it also occurs in patients who wear removable dentures, in whom mucosal erythema is confined to the denture-bearing area.

Systemic or topical antifungal drugs are necessary to resolve these lesions. In patients who have clinically apparent salivary production, fluconazole (200 mg on the first day, then 100 mg every day for 2 to 4 weeks) is the drug of choice. However, systemic antifungal drugs may not be effective in patients who have severe salivary hypofunction and insufficient saliva to convey the drug from the bloodstream to oral mucosa. In such patients, with remaining natural teeth, *oral* antifungal preparations (troches or pastilles), all of which contain cariogenic amounts of sucrose or glucose, *must not be used* to avoid

FIGURE 433-7. Erythematous oral candidiasis. *Left,* Erythematous candidiasis in a 26-year-old woman with primary Sjögren's syndrome, exhibiting symptomatic angular cheilitis, atrophic mucositis, and lingual papillary atrophy. *Right,* Asymptomatic and normal-appearing mucosa after treatment with appropriate topical antifungal drugs (see text).

TABLE 433-4 PIGMENTATIONS OF THE ORAL MUCOSA (BROWN OR GRAY-BLACK IN COLOR)

INCREASED MELANIN PRODUCTION (FLAT LESIONS)
Oral melanotic macule
Ephelis (vermilion border)
Systemic diseases: Addison's disease, von Recklinghausen's disease of skin, Albright's syndrome, Peutz-Jeghers syndrome
PROLIFERATION OF MELANIN-PRODUCING CELLS (FLAT OR RAISED LESIONS)
Pigmented cellular nevi (benign and premalignant types)
Atypical melanocytic hyperplasia, melanoma in situ, radial growth phase of melanoma
Malignant melanoma
NONMELANIN PIGMENTATION
Amalgam tattoo
Focal deposition of systemically distributed metal (lead, bismuth, mercury, others) usually at sites of chronic inflammation
Systemically administered drugs (chloroquine, minocycline, ketoconazole, cyclophosphamide)

enhancing dental caries. Instead, slow oral dissolution (15 to 20 minutes for 2 weeks to 2 months) of vaginal nystatin tablets (twice daily) or miconazole tablets (50 mg daily), which contain little or no caries-supporting carbohydrates, is safe and effective; patients usually need frequent sips of water to aid in dissolving the tablets. Effective topical or systemic treatment significantly improves oral symptoms. Treatment of denture-associated candidiasis requires concurrent treatment of the denture.

The treatment end point is reached when mucosal burning symptoms cease, the patient can again tolerate acidic or spicy foods, and filiform papillae on the dorsal tongue have returned to normal; this recovery takes 2 to 12 weeks, depending on patients' salivary production and treatment compliance. Recurrence is common in patients with chronic salivary hypofunction or immunosuppression, which necessitates recurring or long-term treatment using a noncariogenic topical antifungal drug that provides a sufficient duration of oral mucosal contact (e.g., nystatin or miconazole tablets).

ANGULAR CHEILITIS

Erythema or crusting of the labial angles is usually caused by *Candida* species (see Fig. 433-7) and is usually associated with intraoral candidiasis. In such cases, topical treatment of the angular cheilitis with clotrimazole (1% cream) must be accompanied by intraoral or systemic antifungal treatment, as described previously.

MUCOCUTANEOUS DISEASES

The mucocutaneous diseases of pemphigus vulgaris, mucous membrane pemphigoid, atrophic or erosive lichen planus, and lupus erythematosus can cause similar-appearing oral lesions. Their diagnosis requires examination of a biopsy specimen by routine histopathology and direct immunofluorescence to identify characteristic deposits of various inflammatory proteins.

The first lesions of pemphigus vulgaris are usually oral mucosal vesicles that rapidly rupture, leaving painful erosions or ulcerations. These are followed by development of skin lesions. Rarely, the lesions remain confined to the mouth (Chapter 447).

Lesions of mucous membrane (cicatricial) pemphigoid are usually confined to the oral mucosa or conjunctivae and occur in patients older than 50 years. They begin as vesicles that quickly rupture, leaving ulcers that are chronic but only moderately symptomatic. Use of topical fluocinonide or clobetasol (0.05% gel or ointment, three times a day, 4 to 12 weeks) for several months, as described for lichen planus, is sometimes sufficient to treat the oral lesions, but some patients also need systemic treatment (Chapter 447).

Oral mucosal lesions of lupus may occur in patients who have systemic lupus erythematosus (SLE), in patients who do not have SLE but later develop that disease, or in patients who do not develop SLE (Chapter 274). In this latter group, the lesions of mucosal lupus may be analogous to the skin lesions of chronic discoid lupus. They take the form of reticular hyperkeratotic figures associated with erythema, often resembling lichen planus, but unlike lichen planus are usually solitary or bilaterally asymmetrical. They can be controlled by topical fluocinonide (0.05%, three times a day, 2 to 4 weeks) or intralesional triamcinolone suspension (5 mg/mL), or respond to systemic treatment of SLE.

Pigmentations

Brown or gray-black macules on the oral mucosa are relatively common and range from benign to highly malignant. They may be caused by localized increase in melanin production, proliferation of melanin-producing cells, or deposition of local or systemically distributed pigmented substances (Table 433-4). Mucosal pigmentation may occur after long-term administration of hydroxychloroquine, minocycline, ketoconazole, methyldopa, or cyclophosphamide. Malignant melanomas can occur at any oral mucosal site, but about 85% develop on the hard palatal mucosa or gingiva, or both. Diagnosis of any of these conditions is usually established by biopsy and knowledge of relevant underlying conditions.

Lesions of Kaposi's sarcoma associated with HIV infection often appear first on the oral mucosa, especially the palate. They begin as macules with a blue or purple color, at which time they must be distinguished from purpura. Later, they spread radially and expand vertically (Chapter 400).

ORAL SOFT TISSUE TUMORS

In addition to squamous carcinoma, a variety of oral benign soft tissue tumors are usually treated by excisional biopsy.

Connective Tissue Hyperplasias

The most common oral soft tissue tumors are small, pedunculated masses of hyperplastic fibrous connective tissue covered by normal-appearing mucosa (Table 433-5). Solitary lesions are usually found on the inside of the cheeks or lips. Similar lesions may be present at the border of an ill-fitting denture or may occur in clusters on the hard palate under an ill-fitting denture (palatal papillomatosis).

Generalized or multifocal enlargement of the gingiva (gingival hyperplasia) may be caused by chronic administration of phenytoin, cyclosporine, and many of the calcium-channel blocking drugs (e.g., diltiazem, verapamil, or nifedipine; Fig. 433-8). It can also be associated with a hereditary defect or be caused by an infiltration of atypical white blood cells in some types of leukemia (particularly acute monocytic leukemia; Chapter 189) or by uncontrolled diabetes mellitus (Chapter 236).

Reactive Hyperplasias

Small masses with surfaces that are ulcerated or only partially covered by normal-appearing mucosa usually represent reactive lesions in the form of pyogenic granulomas (whose frequency increases during pregnancy), peripheral giant cell granulomas, or lymphoid hyperplasia of the lingual or other tonsillar tissue. The granulomas are most often located on the gingiva. Rarely, such lesions may represent a metastatic neoplasm.

Epithelial Tumors

Small, white, wartlike epithelial masses are common and can occur in any area of the oral mucosa (Fig. 433-9). They are occasionally classified as

FIGURE 433-8. Drug-induced gingival hyperplasia. Similar clinical lesions may occur with prolonged use of various drugs or as a hereditary condition (see text).

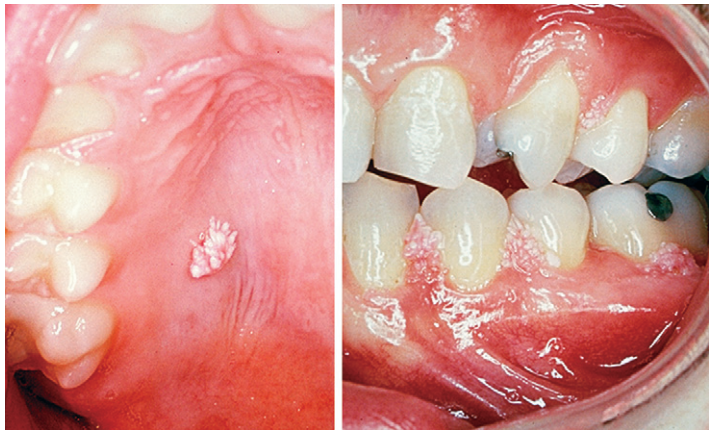

FIGURE 433-9. Papillary epithelial tumors. *Left,* A solitary squamous papilloma. *Right,* multiple gingival papillomas, occurring in all quadrants, from condyloma acuminatum, associated with papilloma virus subtype 6 or 11.

TABLE 433-5 ORAL SOFT TISSUE TUMORS

CONNECTIVE TISSUE HYPERPLASIA (NORMAL-APPEARING OVERLYING MUCOSA)
Irritation fibroma
Denture-associated hyperplasia
Palatal papillomatosis
Generalized gingival hyperplasia
Drug-induced (phenytoin, nifedipine, cyclosporine)
Hereditary
REACTIVE HYPERPLASIA (ERYTHEMATOUS OVERLYING MUCOSA)
Pyogenic granuloma/pregnancy tumor
Peripheral giant cell granuloma
Inflammatory gingival hyperplasia
Hyperplastic lingual tonsil
EPITHELIAL MASSES (USUALLY IRREGULAR WHITE SURFACE)
Papilloma/oral wart
Squamous cell carcinoma
Verrucous carcinoma
Focal epithelial hyperplasia (Heck's disease)
Condyloma acuminatum (venereal wart)
Keratoacanthoma (on lips)
SALIVARY DUCT OBSTRUCTION (MINOR SALIVARY GLANDS)
Mucocele/ranula (usually fluctuant)
Salivary stone (sialolith)
SUBEPITHELIAL NEOPLASMS
Primary connective tissue or salivary gland tumors
Metastatic lesions (especially in the mandible)
Lymphoma (especially in the palate or posterior mandible)
Focal or generalized leukemic infiltrates in the gingiva (especially with acute monocytic leukemia)

TABLE 433-6 CAUSES OF SALIVARY GLAND ENLARGEMENT

USUALLY UNILATERAL
Benign or malignant salivary gland neoplasms (more than 20 different histopathologic types)
Bacterial infection
Chronic sialadenitis (single gland)
USUALLY BILATERAL AND ASSOCIATED WITH SALIVARY HYPOFUNCTION
Viral infection (mumps, cytomegalovirus, influenza, Coxsackie A)
Sjögren's syndrome (benign lymphoepithelial lesion)
Chronic granulomatous diseases (sarcoidosis, tuberculosis, leprosy)
Recurrent parotitis of childhood
Human immunodeficiency virus infection/acquired immunodeficiency syndrome
BILATERALLY SYMMETRICAL, SOFT, NONTENDER, PAROTID ONLY
Sialadenosis (asymptomatic parotid enlargement), idiopathic or associated with:
Diabetes mellitus
Hyperlipoproteinemia
Hepatic cirrhosis
Anorexia/bulimia
Chronic pancreatitis
Acromegaly
Gonadal hypofunction
Phenylbutazone use

epithelial neoplasms, but most do not continue to grow. Human papillomavirus types 2, 6, 11, 13, 32, and 57 have been identified in these wartlike lesions, which are usually classified generically as papillomas. A large wartlike lesion on the oral mucosa should raise the suspicion of verrucous carcinoma.

Mucus Retention Lesions (Mucoceles)

Mucoceles are small, chronic, or recurring vesicles or bullae that occur commonly on the inside of the cheeks and lips, the posterior palate, and the mouth floor. They are caused by injury to one of the many submucosal minor salivary glands, resulting in extravasation of mucus, which causes granulomatous inflammation or blockage of the excretory duct, leading to cyst formation. Both types of lesions require conservative surgical excision because simple incision and drainage are usually followed by recurrence.

SALIVARY GLAND DISEASES

Primary Diseases of Salivary Glands

More than 20 types of benign or malignant neoplasms appear as firm and nontender unilateral or bilateral enlargement of a major gland or as a firm submucosal nodule on the palate or the labial or buccal mucosa (Table 433-6). Their causes are unknown, except for Warthin's tumor (adenolymphoma), which has a strong association with cigarette smoking. Uncommonly, unilateral major gland enlargement may be reactive—for example, chronic sialadenitis from duct obstruction or inadequately treated bacterial sialadenitis. Detection of any of these lesions should be followed by appropriate imaging and biopsy. Both benign and malignant tumors are generally treated by surgery.

Unilateral major salivary gland enlargement that is markedly painful or tender to palpation and has a purulent exudate or nothing expressible from the duct suggests bacterial sialadenitis. Any exudate should be cultured, and initial treatment should be with an oral penicillinase-resistant antibiotic, such as cloxacillin or dicloxacillin, 500 mg, every 6 hours.

Secondary Diseases of Salivary Glands

BILATERAL SALIVARY GLAND ENLARGEMENT AND DECREASED SALIVARY SECRETION ASSOCIATED WITH SYSTEMIC DISEASES

The best-known cause of bilateral salivary gland enlargement is infection by the mumps virus (Chapter 377) in children. However, the prevalence of mumps decreased in the United States by more than 98% after the introduction of an effective vaccine in 1967, and now there are only a few hundred to a few thousand cases per year. Uncommonly, a less acute, mumpslike illness may occur in adults in association with cytomegalovirus (Chapter 384), influenza (Chapter 372), or Coxsackie A (Chapter 387) virus infection.

TABLE 433-7 CAUSES OF DECREASED SALIVARY SECRETION

TEMPORARY
Effects of short-term drug use (e.g., antihistamines)
Virus infections (e.g., mumps)
Dehydration
Psychogenic conditions (e.g., anxiety)
CHRONIC
Effects of chronically administered drugs (particularly antidepressants, monoamine oxidase inhibitors, neuroleptics, parasympatholytics, some combinations of drugs for treating hypertension)
Chronic diseases:
Sjögren's syndrome
Sarcoidosis
Human immunodeficiency virus or hepatitis C infection
Depression
Diabetes mellitus (uncontrolled)
Amyloidosis (primary or secondary)
Central nervous system diseases
Other effects of treatment
Therapeutic radiation to the head and neck
Graft-versus-host disease
Absent or malformed glands (rare)

About 25% of patients with Sjögren's syndrome (Chapter 276) gradually develop chronic bilateral enlargement of major salivary glands, which feel firm and nontender or only slightly tender to palpation. Histologically, the tumors begin as a benign lymphoepithelial lesion (myoepithelial sialadenitis), but after years of chronicity, some transform into an indolent extranodal marginal zone lymphoma or aggressive B-cell lymphoma.

In most patients with Sjögren's syndrome, gradually progressive salivary hypofunction can impair speech and swallowing and cause a characteristic pattern of progressive dental caries that leads to excessive tooth loss if not actively prevented. In severe cases, the oral mucosa becomes dry and sticky, saliva is not expressible from the major ducts, and about one third of patients have signs and symptoms of chronic erythematous candidiasis (see earlier discussion and Fig. 433-7).

The salivary component of Sjögren's syndrome is diagnosed from a labial salivary gland biopsy specimen that contains three to five minor glands and exhibits focal lymphocytic sialadenitis in the absence of nonspecific chronic sialadenitis or another disease, such as noncaseating granuloma. A patient's symptoms of oral dryness (xerostomia) can be caused by a wide variety of conditions (Table 433-7).

Several chronic granulomatous diseases, such as sarcoidosis (Chapter 95), tuberculosis (Chapter 332), and leprosy (Chapter 334), can cause bilateral enlargement and decreased function of salivary glands. The clinical and serologic features of sarcoidosis may occasionally closely mimic those of Sjögren's syndrome, and the distinction is best made by minor salivary gland biopsy.

A few adult patients with HIV infection and most children who are infected in utero develop major salivary gland enlargement and reduced salivary secretion that are caused by lymphocytic infiltration. Parotid gland enlargement usually represents a solid or cystic lymphoepithelial lesion (see Table 433-2).

Recurrent parotitis of childhood includes episodes of unilateral or bilateral parotid enlargement. During flares of this illness, salivary secretion may be reduced, but usually without prominent secondary symptoms or signs. This condition, of unknown cause, usually subsides after puberty.

ASYMPTOMATIC PAROTID ENLARGEMENT (SIALADENOSIS)

Parotid glands can develop bilateral, symmetrical enlargement that is soft and nontender to palpation and associated with normal salivary function (see Table 433-6). Diagnosis is established by this clinical presentation and the presence of one of the systemic diseases known to be associated with it: diabetes mellitus (Chapter 236), hyperlipoproteinemia (Chapter 213), hepatic cirrhosis (Chapter 156), anorexia or bulimia (Chapter 226), chronic pancreatitis (Chapter 146), acromegaly (Chapter 231), and gonadal hypofunction. It can also result from use of phenylbutazone or be a reaction to iodine-containing contrast media. Biopsy of the affected glands is not indicated for diagnosis.

Impaired Salivary Secretion without Gland Enlargement

The common symptom of dry mouth (xerostomia) is most often a side effect of chronically administered drugs. Many classes of drugs reduce unstimulated salivary secretion through anticholinergic or other mechanisms (see Table 433-7). Patients experience these symptoms soon after beginning to use the drug but produce enough saliva during a meal for normal chewing and swallowing. However, the symptoms and associated dental caries are dose dependent and gradually increase with prolonged use of the drug. The classes of drugs producing the most profound effects are most tricyclic antidepressants, most neuroleptics, monoamine oxidase inhibitors, and all anticholinergics. A combination of drugs for treatment of hypertension may also cause symptoms of dry mouth.

Several systemic diseases affect salivary secretion. As noted earlier, most patients with Sjögren's syndrome, some with sarcoidosis, and a few patients with HIV infection experience symptoms of dry mouth to various degrees, with or without salivary gland enlargement. In addition, patients who have primary or secondary *amyloidosis* with salivary gland amyloid deposits may develop impaired secretion. The symptom of xerostomia is more prevalent in individuals who exhibit symptoms of depression but are not taking drugs for its treatment. Studies done before the availability of antidepressant drugs showed that symptoms of depression were associated with decreased salivary secretion.

Irradiation of the head and neck region to treat a malignant tumor usually produces profound dry mouth during therapy. Secretory capacity recovers only slightly in the months following treatment for patients with solid tumors, but recovers significantly for those with multifocal tumors (e.g., Hodgkin's disease).

TREATMENT Rx

Significant chronic salivary hypofunction from any cause produces a risk for dental caries (decay) in approximate proportion to the secretory impairment, but caries can largely be prevented if appropriate measures are taken as soon as the hypofunction begins. Remaining teeth should be protected by a comprehensive dental caries prevention program, monitored by a dentist and including frequent application of appropriate topical fluorides, removal of dental plaque, counseling on control of cariogenic dietary carbohydrates, and placement of appropriate dental restorations as necessary.

Symptomatic treatment of mild to moderately severe salivary hypofunction can include sialagogues such as sugar-free hard candies or chewing gum, regular sips of water, and use of saliva substitutes at night. Symptoms of severe hypofunction can be improved by prescribing cevimeline (30 mg three times a day),[2,3] or pilocarpine (5 mg four times a day), if not contraindicated, but such treatment alone will not prevent dental caries.

Chronic erythematous oral candidiasis is a frequent sequela of chronic salivary hypofunction, and its treatment and retreatment, as noted earlier, substantially improve the patient's oral symptoms.

434 APPROACH TO THE PATIENT WITH NOSE, SINUS, AND EAR DISORDERS

ANDREW H. MURR

Patients with nose, sinus, and ear disorders may have a variety of chief complaints. Nasal symptoms most commonly relate to rhinorrhea or congestion, both of which may be due to allergic, infectious, inflammatory, or structural causes. Sinus disorders, which commonly arise as a feeling of stuffiness or congestion but are sometimes also manifested as pain or even headache (Chapter 405), have a similar set of causes. Common ear complaints include pain, loss of hearing (Chapter 436), and vestibular symptoms (Chapter 436), commonly described by the patient as dizziness but recognized by the physician as vertigo that is different from the lightheadedness that characterizes presyncope and syncope (Chapters 50 and 62). Epistaxis, which is bleeding from the nose, is usually easy to distinguish from hemoptysis from the bronchial tree (Chapter 83) or hematemesis from the gastrointestinal tract (Chapter 137).

Loss of hearing (Chapter 436) and vestibular symptoms (Chapter 436) are discussed elsewhere, as are smell, the related sensation of taste (Chapter 435), and the details of head and neck tumors (Chapter 196). This chapter focuses on the approach to patients with other common nose, sinus, and ear complaints.

NASAL AND SINUS COMPLAINTS

Rhinitis and Sinusitis

DEFINITION

Rhinitis is generally defined as any inflammatory process in the nose, with the common result being a sensation of excess mucous or nasal congestion. The patient may have a sensation of fluid dripping from the nose, either coming from the nose anteriorly or coming from the nose posteriorly. Anterior nasal drainage may be perceived by the patient as being accompanied by an activity such as eating (gustatory rhinitis) and may be visible to an observer. Posterior nasal drainage is more nebulous and subjective, but it is very common and is referred to as postnasal drip.

In general, acute rhinitis and sinusitis describe inflammatory conditions of the nose and sinuses that last less than 4 weeks. Chronic rhinitis and sinusitis persist for more than 3 months despite treatment. Recurrent acute rhinitis and sinusitis are defined by exacerbations that occur four or more times per year and last 7 to 10 days per episode. Subacute rhinitis and sinusitis define symptoms that persist between 4 and 12 weeks and resolve completely with treatment.

EPIDEMIOLOGY

The most common reason for a patient to seek the advice of a physician in the United States concerns problems relating to rhinitis and sinusitis. More than 20 million visits by patients per year are devoted to this complaint, and billions of dollars are spent on medications that are expected to improve the condition.

PATHOBIOLOGY

Humans normally produce about 2 L of mucus per day from their nasal lining. The nose functions primarily as a humidification and filtration system, with a clean and refreshed nasal mucous blanket serving to trap particulate matter and organisms. The nasal and sinus lining consists of ciliated respiratory epithelium; the cilia function in a highly organized and orderly fashion under normal circumstances to transport particulate matter trapped in the mucous blanket in a consistent fashion so that the mucus can be swallowed, thereby avoiding deposition in the bronchi. The nose also serves as the organ of olfaction (Chapter 435) to allow patients to discern tastes and avoid spoiled foods that could cause illness.

The parasympathetic nervous system controls both vascular tone and mucus production in the nose. Inflammatory conditions, such as the common cold, can cause the nasal and sinus lining to swell, thus highlighting the nasal cycle governed by parasympathetic neural control. In a normal state, one side of the nose is relatively decongested and one side is relatively congested because of vascular engorgement. This vascular dilation allows humidification and warming of inspired air and can also affect the ability to discern odors in the process of olfaction. During rhinitis, the inflammation exaggerates the normal relative comparison between the decongested and congested sides of the nose and can be perceived as an uncomfortable nasal stuffiness that shifts from side to side over a period of several hours.

Sinusitis differs from rhinitis in that the term implies an infectious cause rather than physiologic dysfunction. Nevertheless, many different mechanisms of inflammation besides infection may give rise to what is currently generally termed sinusitis.

TABLE 434-1 MAJOR AND MINOR SINUSITIS FACTORS

MAJOR FACTORS	MINOR FACTORS
Facial pain or pressure (in conjunction with other nasal symptoms)	Headache
Facial fullness	Halitosis
Nasal obstruction	Fatigue
Nasal discharge or purulence	Dental pain
Fever (in acute rhinosinusitis)	Fever (in nonacute rhinosinusitis)
	Cough
	Ear pressure or fullness

CLINICAL MANIFESTATIONS

When normal nasal mucosal function is lost, patients often complain of nasal crusting or obstruction, hypersecretion or postnasal drip, coughing, facial pressure, and fatigue. Nasal obstruction that shifts from side to side during the day is common in many types of rhinitis and may be considered an exaggeration of normal physiology.

Major symptoms of sinusitis (Table 434-1) include facial pressure, facial congestion or fullness, nasal obstruction, nasal discharge, and anosmia. Minor symptoms include headache, halitosis, fatigue, dental pain, cough, and ear pressure. Major signs include purulence in the nose noted on examination and, with acute sinusitis, fever. Pain is a frequent complaint with acute sinusitis but infrequent with chronic sinusitis. Patients with chronic sinusitis often note a dull facial pressure that seems to worsen with dependency. Patients with acute sinusitis may have discrete facial pain or dental pain but also have obvious purulent nasal discharge, often with a frank fever. It is important to note that facial pain is not a symptom of chronic sinusitis in the absence of other nasal signs and symptoms. Generally, sinusitis is thought to be present on the basis of at least two major factors, one major factor and two minor factors, or purulence on nasal examination.

DIAGNOSIS

History

A thorough history should probe whether patients have tried over-the-counter or prescription medications, including antihistamines, decongestants, mucolytics, analgesics, mast cell stabilizers, and even steroids, and whether they have helped improve the condition. In addition, other prescription medications have side effects that affect nasal physiology, including birth control pills, antihypertensive medications that cause systemic vasodilation, aspirin, steroids, and antibiotics. Specific questions regarding allergies are important, including seasonality or environmental triggers, the presence or absence of pets, food sensitivities, recent changes in environment, and living conditions, with a focus on old or new carpets, mattresses, furnace filters, or freshly painted interior walls. A patient should be questioned about past allergy skin testing or other testing.

A recent history of other family members or coworkers being ill suggests an infectious process. An astute physician often suspects an infectious process by noting the similarity and time course of symptoms in other patients; this information can be related to patients so that they know what to expect in terms of time course and recovery. A careful past medical history should allow one to determine whether relevant conditions such as previous nasal surgery or trauma, granulomatous diseases, cystic fibrosis (Chapter 89), rheumatologic conditions, immune deficiencies (Chapter 258), or other problems may be contributing factors. Unilateral nasal congestion raises concern for either an anatomic abnormality, such as septal deviation, perhaps related to previous trauma, a polyp or other neoplastic mass, or perhaps even a foreign body.

Physical Examination

The nose should be inspected with a nasal speculum to assess nasal septal anatomy (Fig. 434-1), the most caudal aspect of the inferior turbinates (Fig. 434-2), and the possibility of large nasal polyps (Fig. 434-3) or other masses. In patients with allergic rhinitis, the physical examination may reveal pale and swollen inferior turbinates, whereas copious nasal secretions are more apparent with viral infections. By spraying the nose with a topical decongestant such as phenylephrine (Neo-Synephrine) or oxymetazoline, the middle meatus, which is the air space between the middle turbinate and lateral nasal wall, can often be visualized to assess for nasal polyps or purulent discharge. Examination of the mouth and oropharynx, including the posterior pharyngeal wall, with a tongue blade if necessary, can sometimes identify a stream of postnasal discharge or pus. Sinus palpation and transillumination, though part of the art of medicine, are not sufficiently reliable for diagnosis. The patient's ability to open the mouth without limitation helps exclude trismus, which can sometimes be caused by a deep neck infection.

A complete examination of the head and neck should be performed to look for signs of recent or old trauma such as ecchymosis under the eyelids, swelling of the soft tissue of the face, or deviation of the nasal dorsum. The neck should be palpated for adenopathy (Chapter 171) or other masses.

A basic eye examination should be performed to assess pupillary function, extraocular movements, and possible nystagmus (Chapter 432). An ear examination should be conducted to assess the tympanic membranes bilaterally. In patients with an abnormality of the tympanic membrane or concomitant complaints of hearing loss or disequilibrium (Chapter 436), pneumatoscopy using an air bulb attached to the otoscope can be used to insufflate the ear canal and assess for mobility of the tympanic membrane; decreased mobility suggests a middle ear effusion. Weber and Rinne testing using a 512-Hz tuning fork screens for conductive hearing loss, especially unilateral loss.

Endoscopic examination of the nose, almost always performed by a specialist, is the "gold standard" for evaluating rhinitis and sinusitis. A flexible or rigid fiberoptic scope can allow fine inspection of the septum, turbinates, middle meatus, and sphenoethmoid recess, as well as direct inspection of the nasopharynx, orifice of the eustachian tube, and fossa of Rosenmüller, which is just rostral to the eustachian tube in the nasopharynx and is often the site of origin of nasopharyngeal carcinoma (Chapter 196). Flexible endoscopy can be used to further inspect the oropharynx, larynx, and most of the hypopharynx (Chapter 437).

Laboratory Findings

Cultures

Cultures of the nostril or lower nasal cavity are not typically useful and are not recommended. An endoscopically guided culture of the middle meatus by a specialist may help guide treatment for acutely ill immunocompromised patients, patients with refractory chronic rhinosinusitis, or those whose sinusitis is suspected of causing secondary meningitis, epidural or subdural abscess, brain abscess, orbital involvement, or cavernous sinus thrombosis.

Other Tests

A nasal smear can reveal eosinophils, which is consistent with allergic rhinitis (Chapter 259). Likewise, skin testing or radioallergosorbent testing can help pinpoint allergic triggers (Chapter 257). In patients with acute sinusitis, a white blood cell count with differential may be useful. In patients with chronic sinusitis, serum immunoglobulin levels can be helpful: highly elevated immunoglobulin E (IgE) levels can raise suspicion for allergic fungal sinusitis, whereas low levels of IgG and other subclasses suggest immunodeficiency (Chapter 258). If the patient has chronic nasal crusting as a primary complaint, screening serologic tests for sarcoid (Chapter 95), Wegener's granulomatosis (Chapter 278), T-cell lymphomas (Chapter 191), syphilis (Chapter 327), tuberculosis (Chapter 332), Sjögren's syndrome (Chapter 276), and other chronic inflammatory diseases can be considered. Relatively rare infections such as rhinoscleroma may also be present, so biopsy and cultures may be indicated to help reveal a diagnosis. Use of illicit substances should be considered because cocaine and other illicit drugs may cause nasal crusting. In a patient with a lifelong history of sinusitis since childhood, cystic fibrosis should also be considered (Chapter 89).

(From Dhillon RS, East CA, eds. *Ear, Nose and Throat and Head and Neck Surgery,* 2nd ed. Edinburgh: Churchill Livingstone; 1994:50.)

Imaging

Non–contrast-enhanced computed tomography (CT) is indicated for patients with known or suspected rhinitis and sinusitis. CT is generally performed to document the presence of disease or the effects of treatment to improve the disease. CT is also used to evaluate complications of sinusitis or to investigate sinusitis in immunocompromised patients. Finally, CT is critical before any surgical treatment of the sinuses because of the anatomic information that it provides the surgeon. Opacification or other findings on CT (Fig. 434-4) can often differentiate among the various causes of sinusitis. Plain films have little utility and are not generally recommended. Magnetic resonance imaging (MRI) is occasionally helpful, especially when evaluating tumors or processes that erode bone and are proximate to the brain or eye.

Differential Diagnosis

A rapid onset of symptoms present for a short time suggests a viral upper respiratory infection, especially if the patient also has typical systemic symptoms, such as arthralgia, myalgia, fever, chills, gastrointestinal symptoms, and cough in addition to nasal congestion, postnasal drip, and headache. By comparison, acute bacterial rhinosinusitis causes facial pressure and purulent postnasal discharge. Frequently, viral disease can progress to a secondary bacterial infection, which can become chronic. An acute onset of inhalant allergy is often seasonal or can be traced to a particular precipitant (Chapter 259). Allergic rhinitis typically responds to an empirical trial of antihistamines, whereas viral or bacterial rhinitis does not.

Chronic sinusitis must be differentiated from rhinitis, which is not accompanied by the same degree of incessant inflammation. Types of rhinitis include gustatory rhinitis associated with eating, rhinitis of pregnancy, rhinitis related to abuse of topical vasoconstrictors, rhinitis associated with illicit drug use (e.g., cocaine or methamphetamine), rhinitis of aging, vasomotor rhinitis presumably related to a hypersecretory state mediated by the parasympathetic nervous system, and perennial allergic rhinitis, whose hallmark is a lack of seasonality.

Chronic sinusitis may be caused by chronic viral infection, chronic bacterial infection, chronic fungal infection, and chronic allergy. It is often difficult to pinpoint a specific cause, but the common underlying factor is often inflammatory in nature. Although maxillary antral punctures were used for diagnosis and treatment in the pre-CT era, endoscopically guided culture techniques combined with CT are now the standard of care, except for acute bacterial maxillary sinusitis, for which surgical decompression is desirable, or for some cases of refractory sinusitis in immunocompromised patients or patients in the intensive care unit, where direct culture can guide antibiotic therapy.

Nasal polyps may be caused by Samter's triad (asthma, aspirin sensitivity, and nasal polyposis related to upregulation of leukotrienes caused by prostaglandin blockade). Human papillomavirus (Chapter 381) may cause an inverted papilloma, which responds to surgical excision but can transform to frank malignancy. Polyps are also seen in patients with cystic fibrosis (Chapter 89) and allergic fungal sinusitis, which is manifested by an elevated IgE level, positive fungal cultures (usually for aspergillosis), Charcot-Leyden crystals on histopathology, characteristic densities on CT, and nasal polyposis that is often, but not always unilateral. Antral choanal polyps may extend into the nasal cavity or nasopharynx and cause obstruction.

CT can reveal mucoceles, which are blocked individual sinuses that continue to secrete mucus and can slowly erode bone, expand to involve the eye and brain, or become acutely infected. A mycetoma, which is an isolated "fungus ball" in a sinus, has a characteristic hyperdensity within a sinus opacification. Mycetomas (Chapter 350) are noninvasive but may erode bone via pressure necrosis over a long period. Unilateral nasal polyposis is suggestive of antral choanal polyps, malignancy, inverted papilloma, or allergic fungal sinusitis; early biopsy is recommended. Mucus retention cysts, often present in the maxillary sinus, are manifested as a spherical opacification; an estimated 10% of the population has a mucus retention cyst, which is often asymptomatic.

TREATMENT

Medical Therapy

Viral rhinitis is treated with supportive care, including fluid replacement and treatment of the febrile component of the syndrome with acetaminophen or nonsteroidal anti-inflammatory medications. Steam has a mild decongestant effect, and vitamin C and good nutrition may help hasten the resolution of symptoms. Oral decongestants (such as pseudoephedrine, 120 mg every 12 hours for several days), mucolytics (such as guaifenesin, 200 to 400 mg every 4 to 6 hours for several days), and ipratropium bromide (0.03 or 0.06%, two sprays on each side of the nose every 12 hours for several days) are of potential benefit.

For clinically diagnosed rhinosinusitis, antibiotics are of little benefit, except perhaps in patients with a purulent discharge, in whom a diagnosis of bacterial rhinosinusitis based on the history and physical examination is quite inaccurate.[1] Because any benefits of antibiotics are small and the potential side effects are not trivial, they should be reserved for patients with a high probability of bacterial infection.[2] For acute nonrecurrent maxillary sinusitis diagnosed on purely clinical grounds in a primary care setting without fiberoptic nasal endoscopy, neither antibiotics nor topical nasal steroids are beneficial.[3] By comparison, topical nasal steroids are of proven benefit when acute rhinosinusitis is confirmed by either radiography or nasal endoscopy.[4]

Allergic rhinitis (Chapter 259) responds to various antihistamines, such as diphenhydramine hydrochloride (25 to 50 mg every 4 to 6 hours), loratadine (5 mg twice a day or 10 mg a day), cetirizine hydrochloride (10 mg a day), fexofenadine hydrochloride (60 mg twice a day or 120 mg/day), and topical nasal steroids, including triamcinolone acetonide (two sprays [55 µg] to each side of the nose every day), mometasone furoate (two sprays [50 µg] to each naris every day), fluticasone propionate (two sprays [50 µg] to each naris every day), and budesonide (two sprays [32 µg] to each naris every day). Oral steroids such as prednisone and methylprednisolone in various doses are sometimes useful as well. Allergic desensitization is sometimes recommended when a discrete allergen elicits a strong reaction in a patient. Allergic desensitization may specifically be beneficial for some inflammatory disorders, such as allergic fungal sinusitis.[5]

Nasal polyps frequently respond to oral steroids, either in a tapered burst dose or, in rare cases, in small amounts of titrated daily oral steroids such as prednisone or methylprednisolone. Topical steroids may also be efficacious for treating nasal polyps.

Bacterial sinusitis should be treated with antibiotics directed toward *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pneumoniae*, and *Staphylococcus aureus*. Antibiotics such as amoxicillin, 500 mg three times a day, or erythromycin, 500 mg twice a day for 2 to 3 weeks, with subsequent follow-up examination to document resolution are reasonable first-line coverage. β-Lactamase–stable antibiotics are used as a second-line treatment, as are antibiotics that have good anaerobic coverage: amoxicillin with clavulanic acid at 875 mg twice a day for β-lactamase stability or clindamycin at 300 mg three times a day for anaerobic coverage. The use of antifungals, including itraconazole in an oral or aerosolized form and amphotericin B in an aerosolized form, remains controversial in the treatment of chronic sinusitis.

Surgical Therapy

Surgery is recommended in patients with mucoceles, inverted papilloma, antral choanal polyps, juvenile nasopharyngeal angiofibroma, and malignancies. Surgery can correct septal deviations and anatomically related nasal obstruction. Surgery on the inferior turbinates may be beneficial for refractory rhinitis. Surgery for benign nasal polyposis can improve symptomatic control and reduce the need for oral steroids. Functional endoscopic surgery, which is designed to preserve mucociliary function and is performed with endoscopes through the nostril without large incisions, can be useful for recurrent acute sinusitis and chronic rhinosinusitis.

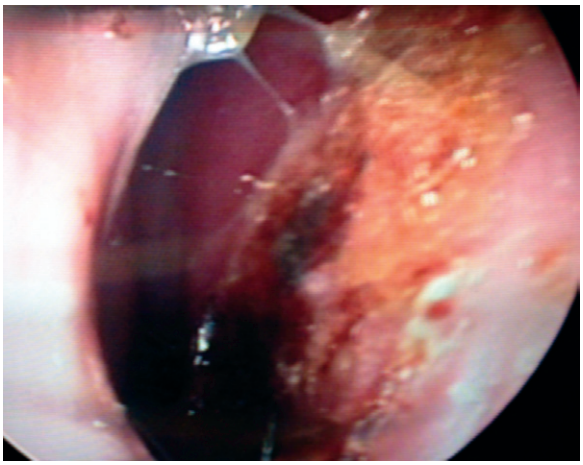

FIGURE 434-5. Dilated nasal vessels and crusting typical of a patient with epistaxis.

TABLE 434-2 CAUSES OF OTALGIA

CAUSES OF OTALGIA	EXTERNAL EAR	MIDDLE EAR	UPPER AERODIGESTIVE TRACT
Likely	Otitis externa Herpes zoster oticus Chondritis Foreign body	Acute otitis media Acute eardrum perforation Barotrauma Chronic otitis media with impending complication	Tonsillitis Tonsil abscess Deep neck abscess Tumor (especially base of the tongue, tonsil, hypopharynx, larynx, nasopharynx)
Unlikely	Malignant otitis externa Tumor	Tumor	

Epistaxis

For a patient with epistaxis, it is first critical to determine the severity of the blood loss. Persistent bleeding may result from warfarin, antiplatelet agents, or any underlying platelet (Chapter 176) or clotting deficiency (Chapter 177). Physical examination should focus on inspection of the anterior septum, which is the most frequent point of origin for epistaxis (see Fig. 434-1). Frequently, dilated blood vessels on the caudal septum can be seen with anterior rhinoscopy (Fig. 434-5). The combination of unilateral otitis media, epistaxis, nasal congestion, and a neck mass would be concerning for nasopharyngeal carcinoma. Rare tumors that can arise with bleeding include juvenile nasopharyngeal angiofibromas in male patients.

Epistaxis can be treated by local pressure, packing (using nasal sponges, balloons, or ½ by 72-inch gauze impregnated with petroleum jelly), humidification, and hydration. Hospitalization and transfusion are rarely required. Offending medications should be reduced in dose or discontinued temporarily if possible. Topical vasoconstrictive medication such as oxymetazoline spray, two sprays on each side of the nose every 12 hours for 3 days, can help prevent persistent epistaxis. Occasionally, lasers or other types of cautery are used to improve the problem. At times, arterial clipping or interventional arterial occlusion can address a specific bleeding area.

EAR PAIN

DEFINITION

Ear pain (Table 434-2) is discomfort perceived by a patient in the area of the temporal bone. Although the discomfort can often be localized by the patient, at times the cause of the discomfort may in fact be distant from the site where the pain is felt. This referred pain can be due to problems in the oral cavity, oropharynx, hypopharynx, or larynx.

PATHOBIOLOGY

The ear is well supplied with sensory nerves and is positioned on the side of the skull. The ear is divided into the outer ear, or pinna, and the ear canal; the middle ear, which encompasses the tympanic membrane and ossicles (Fig. 434-6); and the inner ear, which consists of the cochlea and the vestibular canals, including the utricle and saccule. In general, otalgia is due to problems in the outer or middle ear. The trigeminal nerve innervates the anterior superior quadrant of the pinna, whereas the C2 and C3 cervical cutaneous nerves innervate the rest of the majority of the outer ear. However, there are contributions by the 9th and 10th nerves in the ear canal and even a small patch of sensory innervation by the 7th nerve in the posterior superior ear canal. It is the overlap in distribution of the 9th and 10th cranial nerves that establishes the anatomic basis for referred otalgia in diseases of the oral cavity, oropharynx, and larynx. Therefore, ear pain may be due to inflammatory conditions of the skin of the outer ear, the ear canal, or the middle ear, or it may be due to disease processes unrelated to the ear itself.

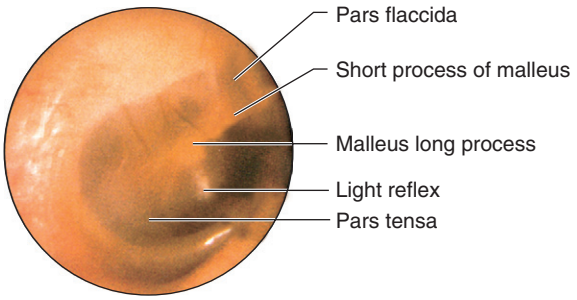

FIGURE 434-6. A normal tympanic membrane. (From Dhillon RS, East CA, eds. *Ear, Nose and Throat and Head and Neck Surgery,* 2nd ed. Edinburgh: Churchill Livingstone; 1994:2.)

CLINICAL MANIFESTATIONS

Patients with ear pain often have complaints referable directly to the ear itself. In cases of otitis externa, frankly obvious erythema and swelling of the skin of the ear canal may be present. Even minute physical manipulation of the ear may be excruciating. In chondritis of the pinna, which may be related to rheumatologic disorders, infection, or trauma, the entire pinna may be swollen and painful. Hearing loss accompanying otalgia may indicate middle ear disease, especially otitis media. Patients sometimes complain of pain in the ear after air travel or driving from a mountainous region. Quick changes in pressure, such as encountered in scuba diving, may indicate barotrauma (Chapter 94), in which the eustachian tube is unable to compensate rapidly enough for the changes in pressure that are encountered. Pain may also be a post-traumatic symptom from relatively minor percussion injury, more severe head trauma, or percussion injury related to a blast. Pain related to noise exposure may also indicate damage to the middle ear or even the inner ear. Deep-seated boring pain over the temporal area accompanied by retro-orbital pain can be due to petrous apex disease, including petrous apicitis.

DIAGNOSIS

History

A patient with ear pain should be asked to reveal the location of the discomfort, the duration of the symptoms, and any activities related to onset of the condition. As an example, recent swimming would make otitis externa ("swimmer's ear") more likely, whereas a recent upper respiratory infection with hearing loss would suggest otitis media. Questions should address possible hearing loss, vertigo, otorrhea, hoarseness, voice change, dysphagia, odynophagia, dyspnea, hemoptysis, hematemesis, and weight loss. A social history with specific concentration on tobacco and alcohol use should be obtained. A possible family history of upper aerodigestive tract and nasopharyngeal carcinoma should be sought. A past surgical history can reveal distant ear or throat surgery.

Physical Examination

A complete head and neck examination, including general assessment for trauma and a basic eye examination, is required. The outer ear and pinna should be examined first. The ear canal should first be palpated and then inspected. An otoscope with a pneumatic bulb attachment is critical to establish the presence or absence of a middle ear effusion. Inspection of the tympanic membrane should be accomplished with notations made about patency and perforation, translucency of the eardrum, position and definition of the malleus, and the eardrum's mobility with the ear canal sealed and a puff of air delivered by the pneumatic bulb. Abnormalities may be caused by infection (Fig. 434-7) or barotrauma (Fig. 434-8). Examination with a 512-Hz tuning fork should be performed to determine lateralization of the sound (Weber test) and whether air conduction is superior to bone conduction (Rinne test). Facial nerve function should be assessed (Chapter 403) by determining

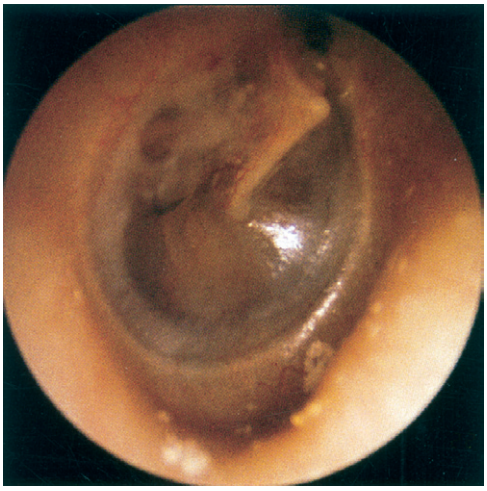

FIGURE 434-7. Otoscopic appearance in otitis media with effusion. The handle and short process of the malleus are brought into relief by retraction of the eardrum. There is a slightly yellow appearance of the eardrum related to the middle ear effusion. (From Dhillon RS, East CA, eds. *Ear, Nose and Throat and Head and Neck Surgery,* 2nd ed. Edinburgh: Churchill Livingstone; 1994:7.)

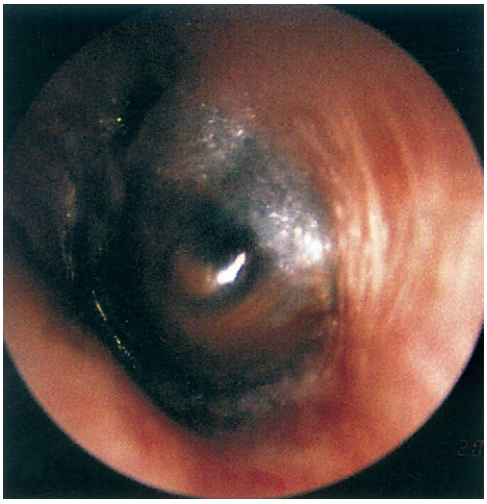

FIGURE 434-8. Blood in the middle ear (hemotympanum). Causes include otitic barotrauma, secretory otitis media, and a high jugular bulb. (From Dhillon RS, East CA, eds. *Ear, Nose and Throat and Head and Neck Surgery,* 2nd ed. Edinburgh: Churchill Livingstone; 1994:26.)

whether the patient can close the eyes. The presence or absence of nystagmus should be recorded. Inspection of the nose, oral cavity, oropharynx, and neck should be accompanied by cranial nerve examination (Chapter 403). Palpation of the tongue and tonsils is especially important if the ear pain is intense and persistent. A careful neck examination should be performed to look for masses. Oral cavity infections (Chapter 433), such as a peritonsillar abscess or severe tonsillitis, may arise as ear pain, and the physical examination should reveal trismus, erythema, mass effect, and other common signs of pharyngitis.

Laboratory

An audiogram can assess hearing loss (Chapter 436). A tympanogram measures compliance of the middle ear system and is an accurate method for diagnosis of otitis media. Cultures are rarely performed because they require tympanocentesis, and cultures of the external ear can reveal a vast variety of organisms that are often treated empirically with antibiotics. If a fever and middle ear effusion are present and neck stiffness is found on physical examination, lumbar puncture may rarely be recommended.

Imaging

In general, imaging is indicated if complications of acute or chronic otitis media are suspected or to look for occult causes of otalgia in the upper aerodigestive tract. If a patient is suspected of having meningitis, epidural or subdural abscess, brain abscess, or sagittal sinus thrombosis, imaging is mandatory. Imaging is also useful for operative planning in patients with chronic otitis media or (rarely) to evaluate for the presence of tumors in the middle or external ear.

Differential Diagnosis

Otitis externa, which is an infection of the skin of the ear canal, is often due to manipulating the ear after swimming or trying to scratch an ear canal that itches because of skin irritation. Patients exhibit erythema of the canal skin and extreme pain on manipulation of the ear canal. In the presence of concomitant cranial neuropathies, especially in diabetic or otherwise immunocompromised patients, malignant otitis externa with osteomyelitis should be suspected. Inspection of the tympanic membrane may reveal fluid (see Fig. 434-7) consistent with otitis media; the tuning fork examination should support the presence of conductive hearing loss. Vesicles on the conchal portion of the pinna, especially when accompanied by facial nerve paralysis, strongly suggest herpes zoster oticus with Ramsay Hunt syndrome (Chapter 383). Perforation of the eardrum suggests either acute or chronic otitis media, traumatic perforation, or possibly cholesteatoma (Chapter 436) if the perforation is in the posterior superior quadrant. Chronic draining otorrhea of long standing with a deep boring pain and perforation of the tympanic membrane suggests a complication of otitis media.

If findings on ear and cranial nerve examination are negative but the patient's complaints of otalgia are persistent, special effort needs to be made to visualize the upper aerodigestive tract, including the nasopharynx, oral cavity, oropharynx, larynx, and hypopharynx, to be sure that infection or tumor is not present in these hard-to-examine areas. MRI can be very useful in these cases.

TREATMENT Rx

Otitis externa is often treated with office suctioning of debris under a microscope and the application of antibiotic drops (ciprofloxacin, tobramycin, neomycin, polymyxin B), with or without hydrocortisone in various combinations. Frequently, a small wick or sponge is placed in the ear canal to help maintain patency of the canal and allow facile application of the medications. For otitis media, oral antibiotic treatment is directed at eradicating *H. influenzae, M. catarrhalis*, *S. pneumoniae*, and *S. aureus* with amoxicillin or erythromycin as for sinusitis (see earlier). The benefit is notable for children 2 years or younger with bilateral otitis and for older children with otitis plus otorrhea, whereas other patients can be observed without antibiotics. In general, antibiotics provide somewhat better short-term outcomes but at the expense of significantly more diarrhea and rashes. Interestingly, the natural history of acute otitis media is acute perforation of the eardrum, which often results in otorrhea and relief of pain. Most middle ear effusions clear spontaneously within 3 months regardless of whether they are treated. Most perforations of an eardrum caused by trauma heal without surgical intervention, but if an eardrum perforation persists for more than about 3 months, surgical closure and the use of tympanoplasty with or without mastoidectomy can be contemplated. Chronic draining perforations, especially if located in the posterior superior quadrant of the tympanic membrane, may require tympanomastoid surgery.

In patients in whom herpes zoster is suspected, acyclovir can be started at 800 mg by mouth five times per day for 7 days, with or without prednisone (Chapter 383). Intracranial complications of otitis media often need to be addressed surgically.

SMELL AND TASTE

ROBERT W. BALOH AND JOANNA JEN

Millions of people suffer from disorders of taste and smell, but these disorders are often neglected because they are not fatal and, unlike abnormalities of vision and hearing, are not considered serious handicaps. Chemosensory disorders, however, often reduce the enjoyment and quality of life and are important to patients who suffer from them.

DEFINITION

The sensory receptor for taste, the taste bud, is made up of 50 to 150 cells arranged to form a pear-shaped organ. The lifespan of these cells is 10 to 14 days, and they are constantly being renewed from dividing epithelial cells surrounding the bud. Taste buds are located on the tongue, soft palate, pharynx, larynx, epiglottis, uvula, and upper third of the esophagus. The taste buds located on the anterior two thirds of the tongue and on the palate are innervated by the chorda tympani branch of the seventh cranial nerve. The ninth cranial nerve innervates the posterior third of the tongue. The 9th and 10th nerves innervate taste buds in the pharynx and larynx. Afferent signals from the taste buds project to the nucleus of the solitary tract in the medulla and then via a series of relays to the thalamus and postcentral somatosensory cerebral cortex (primary ipsilateral). Free nerve endings of the fifth cranial nerve are found on the tongue and in the oral cavity, and lesions involving these pathways can also alter taste perception.

Olfactory receptors lie in a roughly dime-sized area of specialized pigmented epithelium that arches along the superior aspect of each side of the nasal mucosa. Specialized bipolar sensory cells in this region thrust short receptor hairs into the overlying mucosa to detect aromatic molecules as they dissolve. As with taste buds, the specialized receptor portion of the bipolar neuron undergoes continuous renewal, with turnover occurring approximately every 30 days. Thin axons of the bipolar neurons course through small holes in the cribriform plate of the ethmoid bone to form connections in the overlying olfactory bulb on the ventral surface of the frontal lobe. From there, second- and third-order neurons project directly and indirectly to the prepiriform cortex and parts of the amygdaloid complex of both sides of the brain, which represents the primary olfactory cortex.

PATHOBIOLOGY

Pathology

Disorders of taste interfere with digestion because taste stimulants alter salivary and pancreatic flow, gastric contractions, and intestinal motility. Smell also contributes to the anticipation and ingestion of food because much of what is tasted is derived from olfactory stimulation during ingestion and chewing. An inability to detect noxious tastes and odors can result in food or gas poisoning, particularly in elderly subjects. In the extreme, chemosensory disorders can lead to overwhelming stress, anorexia, and depression. Genes that encode for chemoreceptor proteins belong to the G protein–coupled receptor superfamily, which accounts for up to 1% of mammalian genomes. Sequence diversity in these genes encodes unique structural motifs that bind to different ligands signaling different odors and tastes. Distinct and dedicated taste receptor cells express unique receptors to detect each of the five basic tastes: sweet (sensed by the heterodimers T1R1 and T1R3), umami (detected by the heterodimers T1R2 and T1R3), bitter (sensed by an estimated 30 T2Rs), sour (sensed by PKD2L1, with membrane-tethered carbonic anhydrase IV sensing carbonation), and salty. The identity of salt receptors remains unknown. The taste receptor cells transform and transmit information to primary afferents through multiple cranial nerves (VII, IX, and X) via the solitary tract nucleus in the brain stem, with relay in the thalamus, and then onward to the primary cortex (Fig. 435-1).

Pathophysiology

Disorders of taste and smell can be divided into local, systemic, and neurologic categories (Table 435-1). The taste buds and the specialized receptor portion of the bipolar olfactory cells are constantly being renewed, and the

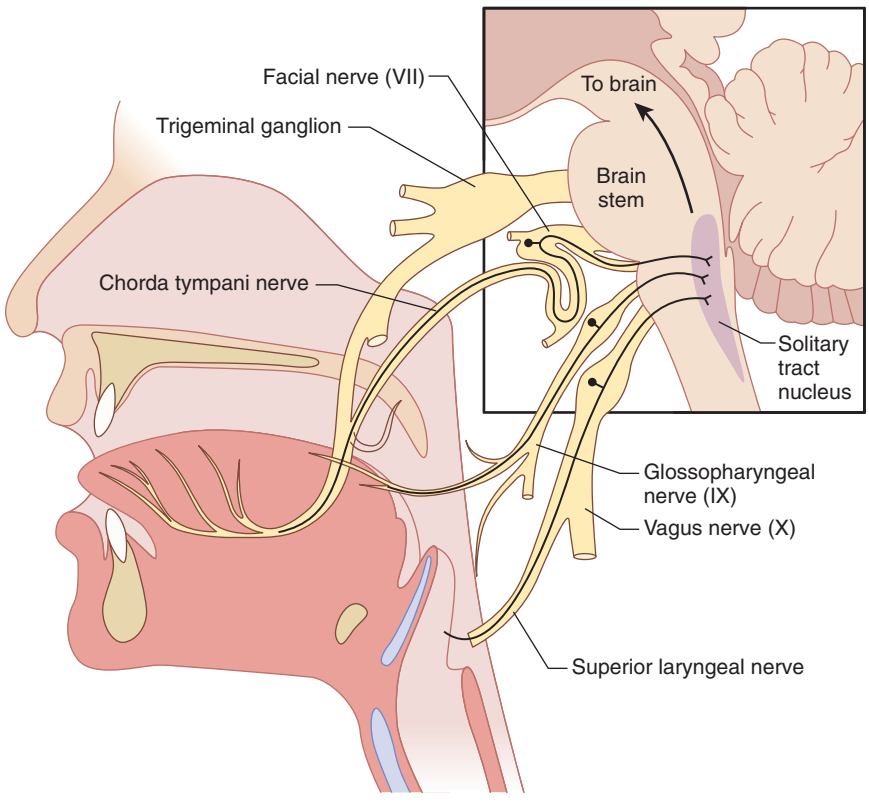

FIGURE 435-1. Anatomy of peripheral taste pathways. Taste information is transmitted from the mouth and the pharynx through multiple cranial nerves that project to the solitary tract nucleus in the brain stem, with relay in the thalamus before reaching the cortex. TABLE 435-1 COMMON CAUSES OF LOSS OF TASTE AND SMELL

	TASTE	SMELL
Local	Radiation therapy, oral infections, dentures, dental procedures	Allergic rhinitis, sinusitis, nasal polyposis, upper respiratory infection
Systemic	Cancer, renal failure, hepatic failure, nutritional deficiency (vitamin B_3, zinc), Cushing's syndrome, hypothyroidism, diabetes mellitus, infection (viral), drugs (antirheumatic and antiproliferative, e.g., corticosteroids, cisplatin, carboplatin, cyclophosphamide, doxorubicin, and methotrexate)	Renal failure, hepatic failure, nutritional deficiency (vitamin B_{12}), Cushing's syndrome, hypothyroidism, diabetes mellitus, infection (viral hepatitis, influenza), drugs (nasal sprays, antihistamines, decongestants, antibiotics, and antirheumatic and antiproliferative drugs that affect taste)
Neurologic	Bell's palsy, familial dysautonomia, multiple sclerosis	Head trauma, multiple sclerosis, Parkinson's disease, Alzheimer's disease, frontal tumor

process of renewal can be affected by nutritional, metabolic, and hormonal states, as well as by therapeutic radiation, drugs, and age. For example, with interruption of mitosis by antiproliferative agents, return of normal taste function takes a minimum of 10 days, whereas return to normal olfactory function takes more than 30 days. Diuretics can block apical ion channels on a taste bud, and antifungal drugs inhibit cytochrome P-450–dependent enzymes at the level of the receptors. Numerous local conditions such as colds and allergies, chronic sinusitis, and nasal polyposis can influence the sense of smell by restricting airway patency. Accidental blows to the head can shear the fine axons of the bipolar olfactory neurons and result in loss of smell. Lesions of the fifth, seventh *(chorda tympani),* and ninth nerves can lead to disordered taste sensation. Olfactory and gustatory disturbances can serve as important diagnostic signs for focal neurologic lesions (e.g., frontal lobe tumors). Hallucinations of smell and taste occur in persons with epileptogenic lesions affecting the mesial temporal lobe and insular region, respectively. Finally, olfactory disturbances and hallucinations occur with a number of psychiatric illnesses (particularly depressive illness and schizophrenia).

CLINICAL MANIFESTATIONS

The most frequently encountered causes of loss of smell are local obstructive disease, viral infections, head injuries (Chapter 406), and normal aging (Chapter 24). Patients can lose their sense of smell not only from chronic allergies and sinusitis (Chapter 434) but also from the nasal sprays and drops that they use to treat these conditions. The most common causes of loss of the sense of taste are viral infections and drug ingestion, particularly antirheumatic and antiproliferative drugs (see Table 435-1). Many of the systemic disorders listed in Table 435-1 probably produce their effect by decreasing the rate of turnover of sensory receptors on the tongue and olfactory epithelia. Disturbances of smell and taste in malnourished patients may be due to specific deficiencies in vitamins and minerals, such as zinc. Viral illnesses such as influenza (Chapter 372) and viral hepatitis (Chapter 150) produce disorders in both taste and smell. Multifocal neurologic disorders such as multiple sclerosis (Chapter 419) can affect the central olfactory and gustatory pathways at multiple levels; as a result, abnormalities in taste and smell are common in such patients. Loss of smell is increasingly being recognized in the early stages of many neurodegenerative disorders, including Parkinson's disease, Alzheimer's dementia, motor neuron disease, and Huntington's disease.

DIAGNOSIS

Olfaction can be tested grossly at the bedside with a few easily recognized odors such as coffee, chocolate, and the roselike aroma of the compound phenylethyl alcohol. Nasal irritants should be avoided. Each nostril is tested separately to determine whether the problem is unilateral or bilateral. Gustatory sensation is typically tested with weak solutions of sugar, salt, and acetic acid, or vinegar. The patient must keep the tongue protruded and respond to questions by nodding the head or by pointing to names of the tastes written on cards. The anterior two thirds and posterior third of the tongue should be tested separately.

TREATMENT

Rx

Treatment of olfactory dysfunction secondary to nasal disease is aimed at opening the air passageways while preserving the olfactory epithelium (Chapter 434). Intranasal steroids for rhinosinusitis (Chapter 434), antibiotics for sinusitis, and therapies for seasonal allergies (Chapter 259) are useful in selected cases. Drugs known to affect taste or smell (Table 435-1) should be discontinued for a trial. Vitamin and mineral therapies are of unproven benefit.

HEARING AND EQUILIBRIUM

ROBERT W. BALOH AND JOANNA JEN

DEFINITION

The neural pathways subserving hearing and those most important for equilibrium and spatial orientation are anatomically proximate in much of their course from their end organs in the inner ear to their termination in the superior portion of the temporal lobe. Because of the close anatomic linkage, disorders that affect hearing often affect equilibrium, and vice versa. For this reason, they are considered together here.

PATHOBIOLOGY

Despite their anatomic propinquity, however, substantial pathophysiologic differences make clinical examination of the two systems quite different. The auditory system is physiologically relatively isolated, so that its function and dysfunction can be tested independently of other neural systems. The vestibular system, in contrast, has many close physiologic links with other neural systems (particularly the visual-oculomotor, somatosensory, and autonomic systems) and can be difficult to test in isolation of these other systems.

DIAGNOSIS

Abnormalities of the auditory system lead to only a few well-defined and unique symptoms (i.e., hearing loss or tinnitus). Abnormalities of the vestibular system can cause symptoms that mimic disorders of other neural structures. Such symptoms include dizziness, visual distortion (oscillopsia), imbalance, nausea, vomiting, and even syncope.

DISORDERS OF THE AUDITORY SYSTEM

DEFINITION

Anatomy and Physiology of Hearing

In normal hearing, sound waves are transmitted from the tympanic membrane through the three ossicles of the air-filled middle ear (air conduction) to the oval window and the basilar membrane of the fluid-sealed cochlea. The ossicles increase the gain from the tympanum to oval window about 18-fold,

compensating for the loss that sound waves moving from air to fluid would otherwise suffer. In the absence of this system, sound may reach the cochlea by vibration of the temporal bone (bone conduction) but with much less efficiency (approximately 60-dB loss). Hair cells, tonotopically organized along the cochlear basilar membrane, detect the vibratory movement of that membrane and transduce vibration into nerve impulses. The nerve impulses are relayed by nerve cells that synapse at the base of hair cells and have their bodies in the spiral ganglion to the cochlear nucleus of the ipsilateral pontine tegmentum. The spiral cochlea mechanically analyzes the frequency content of sound. For high-frequency tones, only sensory cells in the basilar region are activated, whereas for low-frequency tones, all or nearly all sensory cells are activated. Therefore, with lesions of the cochlea and its afferent nerve, the hearing levels for different frequencies are usually unequal, typically resulting in better hearing sensitivity for low-frequency than for high-frequency tones. Within the brain stem, auditory signals ascend from the ventral and dorsal cochlear nuclei to reach the superior olivary nuclei of both sides. Thus, nervous system lesions central to the cochlear nucleus do not cause monaural hearing loss and, conversely, unilateral central lesions do not cause deafness. From these structures, the pathway projects by way of the lateral lemnisci to the inferior colliculi. Each inferior colliculus transmits to the other and to its ipsilateral medial geniculate body, which in turn sends the final projection to the transverse auditory gyrus lying in the superior portion of the ipsilateral temporal lobe.

The normal ear can detect sound frequencies ranging between 20 and 20,000 Hz; the upper range drops off fairly rapidly with advancing age. The ear is most sensitive between 500 and 4000 Hz, which roughly corresponds to the frequency range most important for understanding speech. The hearing level in this range has several practical implications in terms of the degree of handicap and the potential for useful correction with amplification. A 30- to 40-dB hearing level in the speech range would impair normal conversation, whereas an 80-dB hearing level would make everyday auditory communication almost impossible (the social definition of deafness).

PATHOBIOLOGY

Localization of Lesions within the Auditory Pathways

Conductive hearing loss results from lesions involving the external or middle ear. It is typically characterized by an approximately equal loss of hearing at all frequencies and by well-preserved speech discrimination once the threshold for hearing is exceeded. Patients with conductive hearing loss can hear speech in a noisy background better than in a quiet background because they can understand loud speech as well as anyone.

Sensorineural hearing loss results from lesions of the cochlea or auditory division, or both, of the eighth cranial nerve. With sensorineural hearing loss, the hearing levels for different frequencies are usually unequal, typically resulting in better hearing for low- than for high-frequency tones. Patients with sensorineural hearing loss often have difficulty hearing speech that is mixed with background noise and may be annoyed by loud speech. Three important manifestations of sensorineural lesions are diplacusis, recruitment, and tone decay. Diplacusis and recruitment are common with cochlear lesions; tone decay usually accompanies eighth nerve involvement.

Central hearing disorders result from lesions of the central auditory pathways. As a rule, patients with central lesions do not have impaired hearing for pure tones, and they can understand speech as long as it is clearly spoken in a quiet environment. If the listener's task is made more difficult with the introduction of background noise or competing messages, performance deteriorates more markedly in patients with central lesions than in normal subjects.

DIAGNOSIS

Evaluation

Bedside Test

A quick test for hearing loss in the speech range is to observe the response to spoken commands at different intensities (whisper, conversation, shouting). Tuning fork tests permit a rough assessment of the hearing level for pure tones of known frequency. The clinician can use his or her own hearing level as a reference standard. In the Rinne test, nerve conduction is compared with bone conduction by holding a tuning fork (preferably 512 Hz) against the mastoid process until the sound can no longer be heard. It is then placed 1 inch from the ear and, in normal subjects, can be heard about twice as long by air as by bone. If bone conduction is better than air conduction, the hearing loss is conductive, but care must be taken to ensure that the bone conduction is not heard in the normal ear. In the Weber test, the tuning fork is placed on the patient's forehead or upper teeth. Normally, this sound is referred to the center of the head. If it is referred to the side of unilateral hearing loss, the hearing loss is conductive; if it is referred away from the side of unilateral hearing loss, the loss is sensorineural.

Audiometry

Pure tone testing is the cornerstone of most auditory examinations. Pure tones at selected frequencies are presented through either earphones (air conduction) or a vibrator pressed against the mastoid portion of the temporal bone (bone conduction), and the minimal level that the subject can hear (threshold) is determined for each frequency. Two speech tests are routinely used. The *speech reception threshold* (SRT) is the intensity at which the patient can correctly repeat 50% of the words presented. The SRT is a test of hearing sensitivity for speech and should reflect the hearing level for pure tones in the speech range. The *speech discrimination test* is a measure of the patient's ability to understand speech when it is presented at a level that is easily heard. In patients with eighth nerve lesions, speech discrimination scores can be severely reduced, even when pure tone thresholds are normal or nearly normal; by comparison, in patients with cochlear lesions, discrimination tends to be proportional to the magnitude of hearing loss.

Brain stem auditory evoked responses can be recorded from scalp electrodes at 0 to 10 msec (early), 10 to 50 msec (middle), and 50 to 500 msec (late) following a click (a high-frequency stimulus). The early potentials reflect electrical activity at the cochlea, eighth cranial nerve, and brain stem; the later potentials reflect cortical activity. Computer averaging of the responses to 1000 to 2000 clicks separates the evoked potential from background noise. Early evoked responses may be used to estimate the magnitude of hearing loss and to differentiate among cochlea, eighth nerve, and brain stem lesions.

Hearing Loss

PATHOBIOLOGY

Conductive Hearing Loss

The history, examination, and audiometry usually provide the key differential features for identifying common causes of hearing loss (Fig. 436-1). The most common cause of conductive hearing loss is *impacted cerumen* in the external canal. This benign condition is usually first noticed after bathing or swimming when a droplet of water closes the remaining tiny passageway. The most common serious cause of conductive hearing loss is inflammation of the middle ear, *otitis media,* either infective (suppurative; see Fig. 434-7 in Chapter 434) or noninfective (serous). Fluid accumulates in the middle ear, impairing the conduction of airborne sound to the cochlea. Because the air cavity of the middle ear is in direct connection with the mastoid air cells, infection can spread through the mastoid bone and, occasionally, into the intracranial cavity. Chronic otitis media with perforation of the tympanic membrane can result in an invasion of the middle ear and other pneumatized areas of the temporal bone by keratinizing squamous epithelium *(cholesteatoma).* Cholesteatomas can produce erosion of the ossicles and bony labyrinth, resulting in a mixed conductive sensorineural hearing loss. Barotrauma to the middle ear arises with otalgia and hearing loss and can be associated with serous effusion or hematotympanum (see Fig. 434-8 in Chapter 434). *Otosclerosis* commonly produces progressive conductive hearing loss by immobilizing the stapes with new bone growth in front of and below the oval window. The hearing loss is typically conductive, although in some persons the cochlea may be invaded by foci of otosclerotic bone, producing an additional sensorineural hearing loss. Otosclerosis usually stabilizes when the hearing level reaches 50 to 60 dB and rarely progresses to deafness. Other common causes of conductive hearing loss include trauma, congenital malformations of the external and middle ear, and glomus body tumors.

Sensorineural Hearing Loss

Hereditary Deafness

Genetically determined deafness, usually from hair cell aplasia or deterioration, may be present at birth or may develop in adulthood. The diagnosis of *hereditary deafness* rests on the finding of a positive family history. Mutations in connexin 26, a key component of gap junctions in the inner ear, account for most cases of recessively inherited deafness. *Intrauterine factors* resulting in congenital hearing loss include infection (especially rubella); toxic, metabolic, and endocrine disorders; and anoxia associated with Rh incompatibility and difficult deliveries.

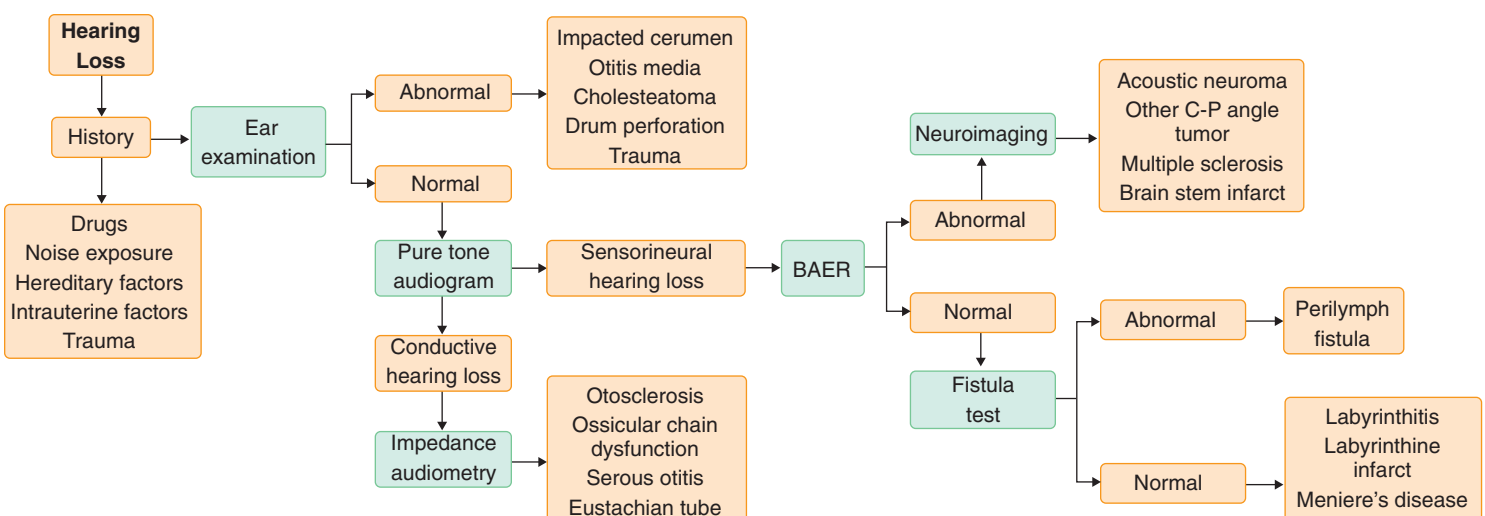

FIGURE 436-1. Evaluation of hearing loss. BAER = brain stem auditory evoked response; C-P = cerebellopontine.

Cochlear Damage

Acute unilateral deafness usually has a cochlear basis. *Bacterial or viral infections* of the labyrinth, *head trauma* with fracture or hemorrhage into the cochlea, or *vascular occlusion* of a terminal branch of the anterior inferior cerebellar artery can extensively damage the cochlea and its hair cells. An acute idiopathic, often reversible, unilateral hearing loss strikes young adults and is presumed to reflect an isolated viral infection of the cochlea and auditory nerve terminals.

Sudden unilateral hearing loss often associated with vertigo and tinnitus can result from a *perilymphatic fistula.* Such fistulas may be congenital or may follow stapes surgery or head trauma.

Drugs

Drugs cause acute and subacute bilateral hearing impairment. Salicylates, furosemide, and ethacrynic acid have the potential to produce transient deafness when taken in high doses. More toxic to the cochlea are aminoglycoside antibiotics (gentamicin, tobramycin, amikacin, kanamycin, streptomycin, and neomycin). These agents can destroy cochlear hair cells in direct relation to their serum concentrations. Some antineoplastic chemotherapeutic agents, particularly cisplatin, cause severe ototoxicity.

Meniere's Disease

Subacute relapsing cochlear deafness occurs with *Meniere's disease,* a condition associated with fluctuating hearing loss and tinnitus, recurrent episodes of abrupt and often severe vertigo, and a sensation of fullness or pressure in the ear. Recurrent endolymphatic hypertension (hydrops) is believed to cause the episodes. Pathologically, the endolymphatic sac is dilated, and the hair cells become atrophic. The resulting deafness is subtle and reversible in the early stages but subsequently becomes permanent and is characterized by diplacusis and loudness recruitment. The disorder is usually unilateral, but in about 20 to 40% of patients, bilateral involvement occurs.

Presbycusis

The gradual, progressive, bilateral hearing loss commonly associated with advancing age is called *presbycusis.* Presbycusis is not a distinct disease entity but rather represents multiple effects of aging on the auditory system. It may include conductive and central dysfunction, although the most consistent effect of aging is on the sensory cells and neurons of the cochlea. The typical audiogram of presbycusis is a symmetrical high-frequency hearing loss gradually sloping downward with increasing frequency. The most consistent pathology associated with presbycusis is degeneration of sensory cells and nerve fibers at the base of the cochlea.

Noise

The recurrent trauma of *noise-induced hearing loss* affects approximately the same region at the base of the cochlea and is also common, particularly among those with exposure to loud explosive or industrial noises. Loud, blaring, modern music has become a recent offender. The loss almost always begins at 4000 Hz and does not affect speech discrimination until late in the disease process. With only brief exposure to loud noise (hours to days), there may be only a temporary threshold shift, but with continued exposure, permanent injury begins. The duration and intensity of exposure determine the degree of permanent injury.

Acoustic Neuroma

Progressive unilateral hearing loss, which arises insidiously, initially in the high frequencies, and worsens by almost imperceptible degrees, is characteristic of benign neoplasms of the cerebellopontine angle, most commonly *acoustic neuromas.* In about 10% of cases, the hearing loss can be acute, apparently owing to either hemorrhage into the tumor or compression of the labyrinthine vasculature. Magnetic resonance imaging (MRI) with contrast reliably identifies small acoustic neuromas.

Central Hearing Loss

Central hearing loss is unilateral only if it results from damage to the pontine cochlear nuclei on one side of the brain stem from conditions such as *ischemic infarction* of the lateral brain stem (e.g., occlusion of the anterior inferior cerebellar artery [Chapter 414]), a plaque of *multiple sclerosis* (Chapter 419), or, rarely, invasion or compression of the lateral pons by a *neoplasm* or *hematoma* (Chapters 195 and 406). Bilateral *degeneration* of the cochlear nuclei accompanies some of the rare recessive inherited disorders of childhood. As noted, clinically important unilateral hearing loss never results from neurologic disease arising rostral to the cochlear nucleus. Although bilateral hearing loss could, in theory, result from bilateral destruction of central hearing pathways, in practice this is rare because involvement of neighboring structures in the brain stem or hemisphere would usually produce overwhelming neurologic disability.

TREATMENT

If an underlying disorder has not yet destroyed the auditory system and can be ameliorated medically or surgically, hearing may be improved or preserved. Most patients with otosclerosis respond to stapedectomy. Closure of a perilymph fistula may improve hearing. Antibiotic and decongestive treatment of otitis media (Chapter 434) should prevent permanent hearing loss. A brief course of high-dose steroids followed by rapid taper is commonly used for patients with idiopathic sudden unilateral sensorineural deafness, but the evidence to support this approach is limited. A low-salt diet and diuretics are effective in selected cases of Meniere's disease. Folic acid supplementation appears to reduce the rate of hearing loss in the elderly. Hearing aids amplify sound, usually with the goal of making speech intelligible. Patients with conductive hearing loss require simple amplification, but those with sensorineural hearing loss often need frequency-selective amplification to make hearing aids useful. Advances in acoustic technology have markedly improved the outlook for the latter. Serial audiograms in patients with noise or ototoxic drug exposure are critical for prevention of permanent hearing loss.

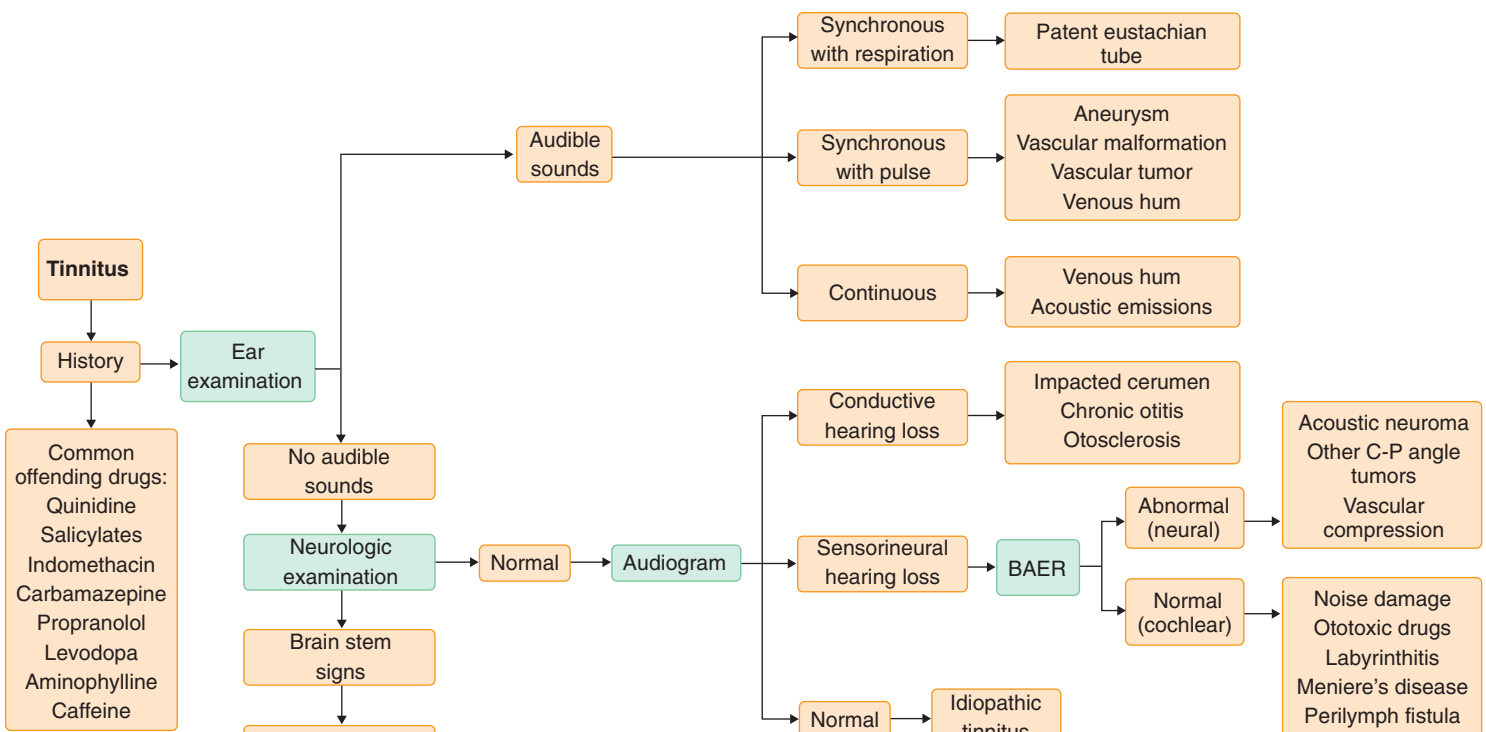

FIGURE 436-2. Evaluation of tinnitus. BAER = brain stem auditory evoked response; C-P = cerebellopontine.

Tinnitus

DIAGNOSIS

The evaluation of common causes of tinnitus (Fig. 436-2) begins with a careful history to identify common offending drugs.

Objective Tinnitus

With *objective tinnitus,* the patient hears a sound arising external to the auditory system, a sound that can usually be heard by the examiner with a stethoscope. Objective tinnitus usually has benign causes such as noise from temporomandibular joints, opening of eustachian tubes, or repetitive muscle contractions. Sometimes, in a quiet room, the patient can hear the pulsatile flow in the carotid artery or a continuous hum of normal venous outflow through the jugular vein. The latter can be obliterated by compression of the jugular vein or extreme lateral rotation of the neck. Pathologic objective tinnitus occurs when patients hear turbulent flow in vascular anomalies or tumors (e.g., glomus jugulare tumor). Objective tinnitus may also be an early sign of increased intracranial pressure. Such tinnitus, which probably arises from turbulent flow through compressed venous structures at the base of the brain, is usually overshadowed by other neurologic abnormalities.

Subjective Tinnitus

Subjective tinnitus can arise from sites anywhere in the auditory system. The sounds most frequently reported are metallic ringing, buzzing, blowing, roaring, or, less often, bizarre clanging, popping, or nonrhythmic beating. Tinnitus heard as a faint, moderately high pitched, metallic ring can be observed by almost anyone who concentrates attention on auditory events in a quiet room. Sustained louder tinnitus accompanied by audiometric evidence of deafness occurs in association with both conductive and sensorineural hearing loss. Tinnitus observed with otosclerosis tends to have a roaring or hissing quality, and that associated with Meniere's disease often produces sounds that vary widely in intensity with time and quality, sometimes including roaring or clanging. Tinnitus with auditory nerve lesions tends to be higher pitched and ringing in quality. Audiometric and brain stem evoked response testing can help distinguish between lesions involving the conducting apparatus, the cochlea, and the auditory nerve. Tinnitus without observable deafness appears sporadically and for variable lengths of time in many persons without other evidence of an ongoing pathologic process.

TREATMENT

Most patients with tinnitus can be helped by a careful evaluation to exclude serious underlying conditions and by subsequent reassurance when appropriate. Often, exacerbating factors such as chronic anxiety and depression can be treated. In patients with hearing loss and tinnitus, a hearing aid may improve tinnitus because the amplification of ambient sound may effectively mask the tinnitus. This mechanism probably explains the frequent observation that removal of cerumen from the external auditory canal to improve ambient hearing also improves tinnitus. Also, when cerumen is attached to the tympanic membrane, tinnitus may result from local mechanical effects on the conductive system. For patients who find their tinnitus most obtrusive when trying to sleep, a bedside frequency modulation (FM) clock radio tuned between stations can provide an effective masking sound; some such radios can be programmed to switch off after the patient falls asleep. A careful drug history should be taken (see Fig. 436-2), and a drug-free trial period should be considered when possible. Benzodiazepines (e.g., diazepam, 2 to 5 mg every 8 hours) or tricyclic amines (e.g., amitriptyline, 25 to 75 mg at bedtime) may provide temporary symptomatic relief of tinnitus, but cognitive behavioral therapy is a more effective long-term approach.

Equilibrium-Vestibular System

PATHOBIOLOGY

Anatomy and Physiology of the Vestibular System

The paired vestibular end organs lie within the temporal bones next to the cochlea. Each organ consists of three semicircular canals that detect angular acceleration and two otolith structures, the utricle and saccule, that detect linear acceleration (including gravitational). Like the cochlea, these organs possess hair cells that act as force transducers, converting the forces associated with head acceleration into afferent nerve impulses. The hair cells of the three semicircular canals, each of which is oriented at right angles to the others, are located in the crista, where their cilia are embedded in a gelatinous mass called the *cupula*. Movement of the head causes the endolymph to flow either toward or away from the cupula, bending the cilia and, depending on the direction of endolymphatic movements, either exciting or inhibiting the afferent nerves at the base of the hair cells. Because the afferent nerves are tonically active, the baseline activity can be increased or decreased

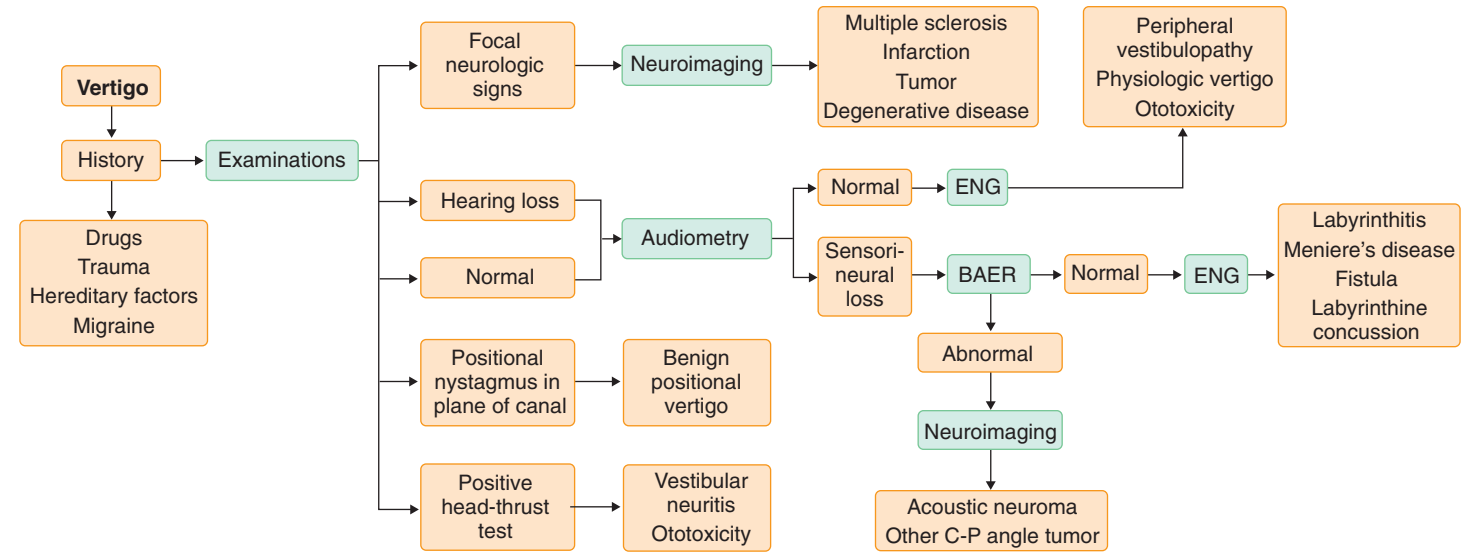

FIGURE 436-3. Evaluation of vertigo. BAER = brain stem auditory evoked response; C-P = cerebellopontine; ENG = electronystagmography.

depending on the direction of hair cell bending. Furthermore, the two sets of semicircular canals are approximately mirror images of each other, so that rotational movement of the head that excites one canal inhibits the analogous canal on the opposite side. The hair cells of the utricle and saccule are located in an area called the *macule.* The macule of the utricle lies approximately in the plane of the horizontal canal, and the macule of the saccule is approximately in the plane of the anterior canal. The hair cell cilia are embedded in a membrane that contains calcium carbonate crystals or otoliths; the density of otoliths is considerably greater than that of the endolymph. Linear accelerations of the head combine with the linear acceleration of gravity to distort the otolith membrane, thereby bending the cilia of the hair cells and modulating the activity of the afferent nerve terminals at the base of the hair cells.

The afferent vestibular nerves have their cell bodies in Scarpa's ganglion. The nerve fibers travel in the vestibular portion of the eighth cranial nerve contiguous to the acoustic portion. Fibers from different receptor organs terminate in different vestibular nuclei at the pontomedullary junction. There are also direct connections with many portions of the cerebellum, the greatest representation being in the flocculonodular lobe, the so-called vestibular cerebellum. Efferent fibers from the brain stem travel through the vestibular nerve to reach hair cells of the semicircular canals and macules, where they modulate afferent activities. From the vestibular nuclei, second-order neurons make important connections to the vestibular nuclei of the other side, to the cerebellum, to motor neurons of the spinal cord, to autonomic nuclei in the brain stem, and, most important for the examining clinician, to the nuclei of the oculomotor system. Fibers from the vestibular nuclei also ascend through the brain stem and thalamus to reach the cerebral cortex bilaterally.

DIAGNOSIS

Evaluation

History

Most vestibular problems presented to the physician are episodic, and often there are neither symptoms nor signs when the physician examines the patient. The history, therefore, can become paramount for identifying vestibular dysfunction. The history should attempt to distinguish vertigo (the illusion of movement in space) from lightheadedness (presyncope), ataxia (disequilibrium of the body without true movement in space), and psychogenic symptoms (the feeling of dissociation or, sometimes, disequilibrium).

Vertigo can be caused by either the peripheral or central vestibular apparatus. In general, peripheral vertigo is more severe, is more likely to be associated with hearing loss and tinnitus, and often leads to nausea and vomiting. Nystagmus associated with peripheral vertigo is usually inhibited by visual fixation. Central vertigo is generally less severe than peripheral vertigo and is often associated with other signs of central nervous system disease. The nystagmus of central vertigo is not inhibited by visual fixation and frequently is prominent when vertigo is mild or absent.

Common Causes of Vertigo

Physiologic Vertigo

Physiologic vertigo includes common disorders that occur in healthy people such as *motion sickness, space sickness,* and *height vertigo* (Fig. 436-3). In these conditions, vertigo (defined as an illusion of movement) is minimal while autonomic symptoms predominate. With height vertigo, patients may experience acute anxiety and panic reaction. Individuals with motion sickness and space sickness typically develop perspiration, nausea, vomiting, increased salivation, yawning, and generalized malaise. Gastric motility is reduced and digestion impaired. Even the sight or smell of food is distressing. Hyperventilation is a common sign, and the resulting hypocapnia leads to changes in blood volume, with pooling in the lower parts of the body predisposing to postural hypotension and syncope. An unusual variant of motion-induced dizziness occurs when the subject returns to stationary conditions after prolonged exposure to motion *(mal de debarquement syndrome).* Typically, affected patients report that they feel the persistent rocking sensation of a boat long after returning to solid ground. Rarely, the syndrome can last for months to years after exposure to motion and can even be incapacitating. The cause is unknown.

Physiologic vertigo can often be suppressed by supplying sensory cues that help to match the signals originating from different sensory systems. Thus, motion sickness, which is caused by a mismatch of visual and vestibular signals, is exacerbated by sitting in a closed space or reading (giving the visual system the miscue that the environment is stationary). It may be improved by looking out at the horizon. Height vertigo, caused by a mismatch between sensation of normal body sway and lack of its visual detection, can often be relieved either by sitting or by visually fixating a nearby stationary object.

Benign Positional Vertigo (Canalithiasis)

Benign positional vertigo is by far the most common cause of vertigo. Patients with this condition develop brief episodes of vertigo (less than 1 minute) with position change, typically when turning over in bed, getting in and out of bed, bending over and straightening up, or extending the neck to look up (so-called top-shelf vertigo). Benign positional vertigo results when otolith debris inadvertently enters one of the semicircular canals. It can occur after head trauma or inner ear infection but most commonly occurs spontaneously in older people. The diagnosis rests on finding characteristic positional nystagmus in the plane of the affected canal (see later). It is important to recognize this syndrome because, in most patients, it can be cured by simple bedside maneuvers (Fig. 436-4). If the history or findings are atypical, the condition must be distinguished from other causes of positional vertigo that may occur with tumors or infarcts of the posterior fossa.

Acute Peripheral Vestibulopathy (Vestibular Neuritis)

One of the most common clinical neurologic syndromes at any age is the acute onset of vertigo, nausea, and vomiting lasting for several days and not associated with auditory or neurologic symptoms. A viral origin is suspected,

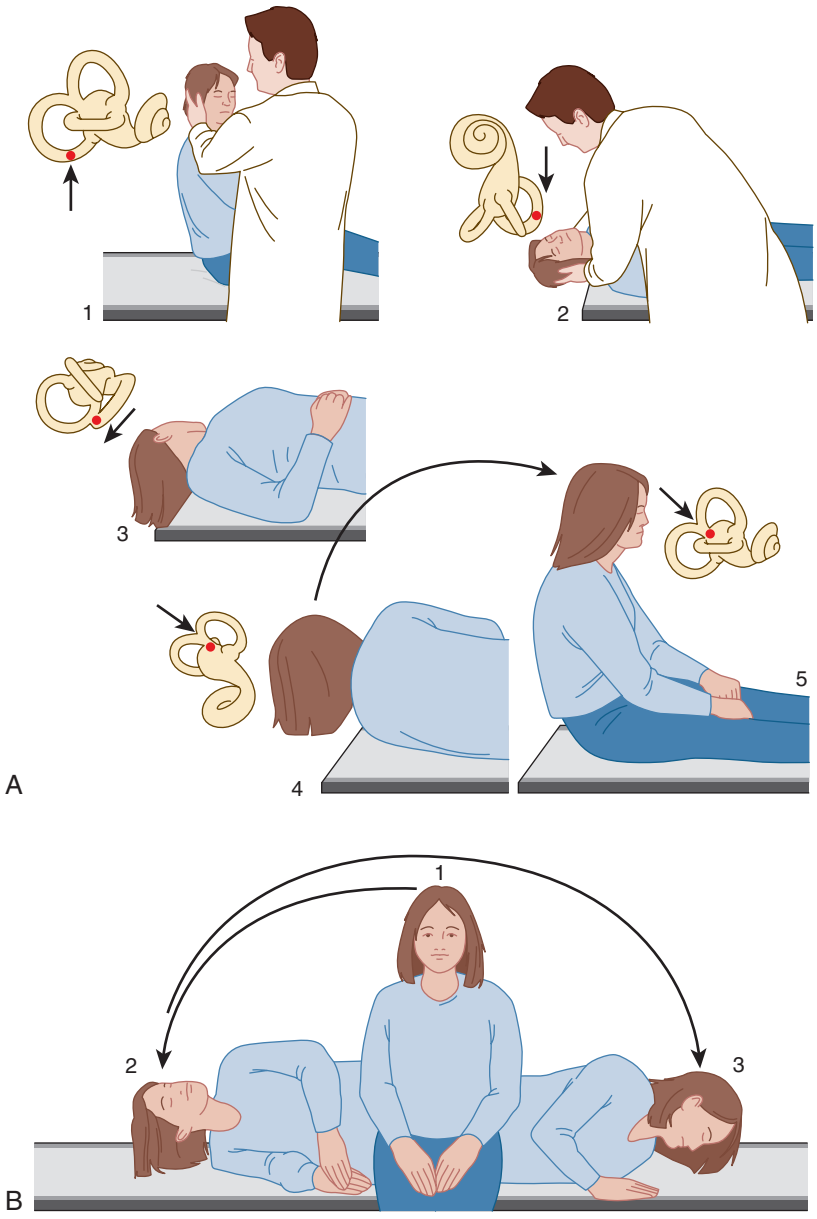

FIGURE 436-4. Modified Epley's (A) and Semont's (B) maneuvers for benign positional vertigo affecting the right posterior semicircular canal (PSC). The procedure is reversed for treating the left PSC. The entire sequence should be repeated until no nystagmus is elicited. (From Fife TD, Iverson DJ, Lempert T, et al. Practice parameter: therapies for benign paroxysmal positional vertigo [an evidence-based review]: report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology.* 2008;70:2067-2074.)

but attempts to isolate an agent have been unsuccessful, except for occasional findings of a herpes zoster infection. Pathologic studies showing atrophy of one or more vestibular nerve trunks, with or without atrophy of their associated sense organs, are evidence of a vestibular nerve site and, probably, viral cause for many patients with this syndrome. Many patients report an upper respiratory tract illness 1 to 2 weeks before the onset of vertigo. This syndrome occasionally occurs in epidemics (epidemic vertigo), may affect several members of the same family, and more often erupts in the spring and early summer. Most affected patients gradually improve over 1 to 2 weeks, but residual dizziness and imbalance can persist for months.

Meniere's Disease

Meniere's disease (see earlier) accounts for about 10% of all patients with vertigo. The diagnosis is based on documenting episodic severe attacks accompanied by fluctuating hearing levels on audiometric testing beginning in the low frequencies.

Migraine

Vertigo is a common symptom with migraine (Chapter 405). It can occur with headaches or in separate isolated episodes, and it can predate the onset of headache. So-called benign paroxysmal vertigo of childhood is often the first symptom of migraine. The mechanism of vertigo with migraine is not clear, but damage to the inner ear occurs in about one fourth of patients. A few develop typical features of Meniere's disease.

Post-traumatic Vertigo

Vertigo, hearing loss, and tinnitus often follow a blow to the head (Chapter 406) that does not result in temporal bone fracture, termed *labyrinthine concussion.* Although they are protected by a bone capsule, the delicate labyrinthine membranes are susceptible to blunt trauma. Blows to the occipital or mastoid region are particularly likely to produce labyrinthine damage. *Transverse fractures* of the temporal bone typically pass through the vestibule of the inner ear, tearing the membranous labyrinth and lacerating the vestibular and cochlear nerves. Complete loss of vestibular and cochlear function is the usual sequela, and the facial nerve is interrupted in approximately 50% of cases. Examination of the ear often reveals hemotympanum (see Fig. 434-8 in Chapter 434), but bleeding from the ear seldom occurs because the tympanic membrane usually remains intact. As noted earlier, *benign positional vertigo* is also a common sequela of head trauma. *Fistulas* of the oval and round windows can result from impact noise, deep-water diving, severe physical exertion, or blunt head injury without skull fracture. The mechanism of the rupture is a sudden negative or positive pressure change in the middle ear or a sudden increase in cerebrospinal fluid pressure transmitted to the inner ear through the cochlear aqueduct and internal auditory canal. Clinically, the rupture leads to the sudden onset of vertigo or hearing loss, or both. Surgical exploration of the middle ear is warranted when there is a clear relationship between the onset of vertigo or hearing loss, or both, and the onset of severe exertion, barometric change, head injury, or impact noise.

Postconcussion Syndrome

The so-called postconcussion syndrome refers to a vague dizziness (rarely vertigo) associated with anxiety, difficulty in concentrating, headache, and photophobia induced by a head injury resulting in concussion (Chapter 406). Occasionally, similar but less pronounced symptoms are associated with mild head injury judged to be trivial at the time. The cause is unknown, but animal studies indicate that small multifocal brain lesions (petechiae) commonly occur after concussive brain injury.

Other Peripheral Causes of Vertigo

Vertigo can be associated with *chronic bacterial otomastoiditis,* either from direct invasion of the inner ear by the bacteria or by erosion of the labyrinth by a cholesteatoma. Radiographic studies of the temporal bone readily identify these disorders. *Autoimmune inner ear disease* typically arises with episodic vertigo and fluctuating hearing levels similar to Meniere's disease, but it is more fulminant with early bilateral involvement. It can occur in isolation or with other systemic features of autoimmune disease. About two thirds of patients have antibodies directed against heat shock protein 70. The aminoglycosides streptomycin and gentamicin are remarkably selective for vestibular ototoxicity. The patient may suffer acute vertigo if the toxic effect is asymmetrical. More often, there is a progressive symmetrical loss of vestibular function leading to imbalance but not vertigo. Unfortunately, many patients being treated with ototoxic drugs are initially bedridden and unaware of the vestibular impairment until they recover from their acute illness and try to walk. They then discover that they are unsteady on their feet and that the environment tends to jiggle in front of their eyes *(oscillopsia)*. The diagnosis can be made at the bedside with a head-thrust test (bilateral corrective saccades; see later). Caloric and rotational testing can document the degree of vestibular loss. The best treatment is prevention. If the drug is discontinued early during the course of symptoms, the disorder may stabilize or improve.

Vascular Insufficiency

Vertebrobasilar insufficiency is a common cause of vertigo in elderly persons. Whether the vertigo originates from ischemia of the labyrinth, brain stem, or both structures is not always clear because the blood supplies to the labyrinth, eighth cranial nerve, and vestibular nuclei originate from the same source, the basilar vertebral circulation (Chapter 413). Vertigo with *vertebrobasilar insufficiency* is abrupt in onset, usually lasting several minutes, and is frequently associated with nausea and vomiting. Associated symptoms resulting from ischemia in the remaining territory supplied by the posterior circulation include visual illusions and hallucinations, drop attacks and weakness, visceral sensations, visual field defects, diplopia, and headache. These symptoms occur in episodes either in combination with the vertigo or alone. Vertigo may be an isolated initial symptom of vertebrobasilar ischemia, but repeated episodes of vertigo without other symptoms should suggest another diagnosis. Vertebrobasilar insufficiency is usually caused by atherosclerosis of the subclavian, vertebral, and basilar arteries. Occasionally, episodes of vertebrobasilar insufficiency are precipitated by postural hypotension, Stokes-Adams attacks, or mechanical compression from cervical spondylosis. MRI of the brain is usually normal because the vascular insufficiency is transient and function returns to normal between episodes. MR angiography can identify occlusive vascular disease most commonly involving the vertebral-basilar junction.

Vertigo is a common symptom with *infarction of the lateral brain stem* or *cerebellum* (Chapter 414), or both. The diagnosis is usually clear, based on the characteristic acute history and pattern of associated symptoms and neurologic findings. Occasionally, cerebellar infarction or hemorrhage arises with severe vertigo, vomiting, and ataxia without associated brain stem symptoms and signs that might suggest the erroneous diagnosis of an acute peripheral vestibular disorder. The key differential is the finding of clear cerebellar signs (extremity and gait ataxia) and of direction-changing, gaze-evoked nystagmus. Such patients must be watched carefully for several days because they may develop progressive brain stem dysfunction owing to compression by a swollen cerebellum.

Cerebellopontine Angle Tumors

Most tumors growing in the cerebellopontine angle (e.g., *acoustic neuroma, meningioma, epidermal cyst*) grow slowly, allowing the vestibular system to accommodate so that they produce only a vague sensation of disequilibrium rather than acute vertigo (Chapter 195). Occasionally, however, episodic vertigo or positional vertigo heralds the presence of a cerebellopontine angle tumor. In virtually all patients, retrocochlear hearing loss is present, best identified by audiometric testing. MRI with contrast is the most sensitive diagnostic study for identifying a cerebellopontine angle tumor.

Other Central Causes of Vertigo

Acute vertigo may be the first symptom of *multiple sclerosis* (Chapter 419), although only a small percentage of young patients with acute vertigo eventually develop multiple sclerosis. Vertigo in multiple sclerosis is usually transient and often associated with other neurologic signs of brain stem disease, in particular, internuclear ophthalmoplegia or cerebellar dysfunction. Vertigo may also be a symptom of *parainfectious encephalomyelitis* or, rarely, *parainfectious cranial polyneuritis.* In this instance, the accompanying neurologic signs establish the diagnosis. The *Ramsay Hunt syndrome* (geniculate ganglion herpes) is characterized by vertigo and hearing loss associated with facial paralysis and, sometimes, pain in the ear. The typical lesions of herpes zoster (Chapter 383), which may follow the appearance of neurologic signs, are found in the external auditory canal and over the palate in some patients. Rarely is herpes zoster responsible for vertigo in the absence of the full-blown syndrome. *Granulomatous meningitis* (Chapter 420) or *leptomeningeal metastasis* and cerebral or systemic *vasculitis* (Chapter 278) may involve the eighth nerve, producing vertigo as an early symptom. In these disorders, cerebrospinal fluid analysis usually suggests the diagnosis (Chapter 403). Patients suffering from *temporal lobe epilepsy* (Chapter 410) occasionally experience vertigo as the aura. Vertigo in the absence of other neurologic signs or symptoms is never caused by epilepsy or other diseases of the cerebral hemispheres.

Bedside Tests

Hyperventilation

If the history is not clear, bedside provocative tests to mimic the symptom may assist in making a pathophysiologic diagnosis. Hyperventilation, which lowers the arterial partial pressure of carbon dioxide ($Paco_2$) and decreases cerebral blood flow, causes a lightheaded sensation associated with syncope. Patients with compressive lesions of the vestibular nerve, such as with an acoustic neuroma or cholesteatoma, or with demyelination of the vestibular nerve root entry zone may develop vertigo and nystagmus after hyperventilation. Presumably, metabolic changes associated with hyperventilation trigger the partially damaged nerve to fire inappropriately.

Vestibulospinal Function

Bedside tests of vestibulospinal function are often insensitive because most patients can use vision and proprioceptive signals to compensate for any vestibular loss. Patients with acute unilateral peripheral vestibular lesions may past-point or fall toward the side of the lesion, but within a few days, balance returns to normal. Patients with bilateral peripheral vestibular loss have more difficulty compensating and usually show some imbalance on the Romberg and tandem walking tests (Chapter 403), particularly with eyes closed.

Doll's-Eye and Head-Thrust Tests

The vestibulo-ocular reflex can be tested at the bedside using the doll's-eye and head-thrust tests. In an alert human, rotating the head back and forth in the horizontal plane induces compensatory horizontal eye movements that are dependent on both the visual and vestibular systems. The doll's-eye test is a test of vestibular function in a comatose patient (Chapter 411) because such patients cannot generate pursuit or corrective fast components. In this setting, conjugate compensatory eye movements indicate normally functioning vestibulo-ocular pathways. Because the vestibulo-ocular reflex has a much higher frequency range than the smooth pursuit system, a qualitative bedside test of vestibular function can be made with the *head-thrust test.* It is performed by grasping the patient's head and applying brief, small-amplitude, high-acceleration head thrusts first to one side and then the other. The patient fixates on the examiner's nose and the examiner watches for corrective saccades, which are a sign of an inappropriate compensatory slow phase.

Caloric Test

The caloric test induces endolymphatic flow in the horizontal semicircular canal and horizontal nystagmus by creating a temperature gradient from one side of the canal to the other. With a cold caloric stimulus, the column of endolymph nearest the middle ear falls because of its increased density. This

TABLE 436-1 DESCRIPTION, MECHANISM, AND FOCUS OF DIAGNOSTIC WORK-UP FOR COMMON TYPES OF DIZZINESS

TYPE OF DIZZINESS	DESCRIPTION	MECHANISM	FOCUS OF DIAGNOSTIC EVALUATION
Vertigo	Spinning (environment moves), tilt, drunkenness	Imbalance in tonic vestibular activity	Auditory and vestibular systems
Near faint	Lightheaded, swimming	Decreased blood flow to entire brain	Cardiovascular system
Psychophysiologic	Dissociated from body, spinning inside (environment still)	Impaired central integration of sensory signals	Psychiatric assessment
Disequilibrium	Off balance, unsteady on feet	Loss of vestibulospinal, proprioceptive, cerebellar, or motor function	Neurologic assessment

causes the cupula to deviate away from the utricle (ampullofugal flow) and produces horizontal nystagmus with the fast phase directed away from the stimulated ear. A warm stimulus produces the opposite effect, causing ampullopetal endolymph flow and nystagmus directed toward the stimulated ear (a mnemonic is COWS, meaning cold opposite, warm same). Because of its ready availability, ice water (approximately 0° C) can be used for bedside caloric testing. To bring the horizontal canal into the vertical plane, the patient lies in the supine position with head tilted 30 degrees forward. Infusion of 1 to 3 mL of ice water induces a burst of nystagmus usually lasting about a minute. Greater than a 20% asymmetry in nystagmus duration suggests a lesion on the side of the decreased response. The ice water caloric test is a useful way to test the integrity of the oculomotor pathways in a comatose patient. In this case, ice water induces only a slow tonic deviation toward the side of stimulation.

Positional Tests

Examination for pathologic vestibular nystagmus should include a search for spontaneous and positional nystagmus (see Table 432-5 in Chapter 432). Because vestibular nystagmus secondary to peripheral vestibular lesions is inhibited with fixation, the yield is increased by impairing fixation with +30 lenses (Frenzel glasses) or infrared video recordings. Two types of positional testing are typically performed: moving the patient from the sitting to head-hanging-right and head-hanging-left positions (Dix-Hallpike test) and turning the head to the right and left while the patient lies supine. Induced positional nystagmus may be paroxysmal or persistent, and it may be in the same direction in all positions or change directions in different positions. The most common cause of positional nystagmus is otolith debris in the semicircular canals, either free floating (paroxysmal) or attached to the cupula (persistent). This type of nystagmus always occurs in the plane of the affected canal—vertical torsional for the vertical canals and horizontal torsional for the horizontal canal. By contrast, central positional nystagmus is often pure vertical or horizontal and cannot be explained by stimulating a single semicircular canal.

Nystagmography

Nystagmography tests oculomotor control by inducing and recording eye movements. A standard test battery includes (1) tests of visual ocular control (saccades, smooth pursuit, and optokinetic nystagmus), (2) a careful search for pathologic nystagmus with fixation and with eyes open in darkness, and (3) measurement of induced vestibular nystagmus (caloric and rotational). Nystagmography can be helpful in identifying a vestibular lesion and localizing it within the peripheral and central pathways.

Evaluating the "Dizzy" Patient

The history is key because it determines the type of dizziness (vertigo, near-faint, psychophysiologic disequilibrium), associated symptoms (neurologic, audiologic, cardiac, psychiatric), precipitating factors (position change, trauma, stress, drug ingestion), and predisposing illness (systemic viral infection, cardiac disease, cerebrovascular disease; Table 436-1). The history provides direction for both the examination and the diagnostic evaluation. When focal neurologic signs are found, neuroimaging usually leads to a specific diagnosis. When vertigo is present without focal neurologic symptoms or signs, head-thrust and positional testing are key to localizing the lesion to the labyrinth or eighth nerve. Audiometry and nystagmography are useful if the cause of vertigo is not clear after the history and examination. Patients with psychophysiologic dizziness should be identified early so that needless tests are not obtained. A detailed cardiac evaluation (including loop monitoring) often identifies the cause of episodic near fainting (Chapters 50 and 62).

TABLE 436-2 TREATMENT OF COMMON VERTIGO SYNDROMES

SYNDROME	TREATMENT
Benign positional vertigo	
Posterior canal variant	Epley's maneuver (see Fig. 436-4)
Horizontal canal variant	Barbecue roll toward normal side (side with less nystagmus), sleep with normal ear down
Vestibular neuritis	Methylprednisolone, 100 mg × 3 days, gradual taper over 22 days (must start within 3 days of onset)
Meniere's disease	
Medical	Low salt (1-2 g Na^+/day) *and* either hydrochlorothiazide 25-50 mg/day *or* hydrochlorothiazide 25 mg/day plus triamterene 50 mg/day
Surgical	Intratympanic gentamicin, vestibular nerve section

TREATMENT Rx

Treatment of vertigo can be divided into three general categories: specific, symptomatic, and rehabilitative. When possible, treatment should be directed at the underlying disorder. Specific therapies include particle repositioning maneuvers (the Epley and Semont maneuvers; see Fig. 436-4) for benign positional vertigo.[4] For vestibular neuritis, steroids (e.g., methylprednisolone, 1 mg/kg/day for 5 days then tapered over the next 15 days) are effective.[5] For Meniere's disease, a low-salt diet and diuretics (e.g., 25 mg hydrochlorothiazide and 50 mg triamterene daily) (Table 436-2) are effective. Intratympanic gentamicin can significantly reduce vertigo in patients with unilateral Meniere's disease who do not respond to medical treatment.[6]

In many cases, however, symptomatic treatment either is combined with specific therapy or is the only treatment available. Many different classes of drugs have been found to have antivertiginous properties, and in most instances, the exact mechanism of action is uncertain. All these agents produce potentially unpleasant side effects, and the decision concerning which drug or combination to use is based on their known complications and on the severity and duration of the vertigo. An episode of prolonged, severe vertigo is one of the most distressing symptoms that a patient can experience. Affected patients prefer to lie still with eyes closed in a quiet, dark room. Antivertiginous drugs with sedation such as promethazine HCl (25 mg) or diazepam (5 mg) may be helpful. Prochlorperazine suppositories (25 mg) may stop vomiting.

In more chronic vertiginous disorders, when the patient is trying to carry on normal activity, less sedating antivertiginous medications such as meclizine (25 mg) or transdermal scopolamine (0.5 mg every 3 days) may provide relief. Chronic use of these drugs should be avoided.

Vestibular rehabilitation exercises are designed to help the patient compensate for permanent loss of vestibular function.[7] As the acute stage of nausea and vomiting subsides, the patient should attempt to focus the eyes and to move and hold them in the direction that provokes the most dizziness. A useful exercise involves staring at a visual target while oscillating the head from side to side or up and down, slow at first and then fast. The patient should try to stand and walk, at first in contact with a wall or with an assistant, and make slow supported turns. As improvement occurs, head movements should be added while standing and walking.

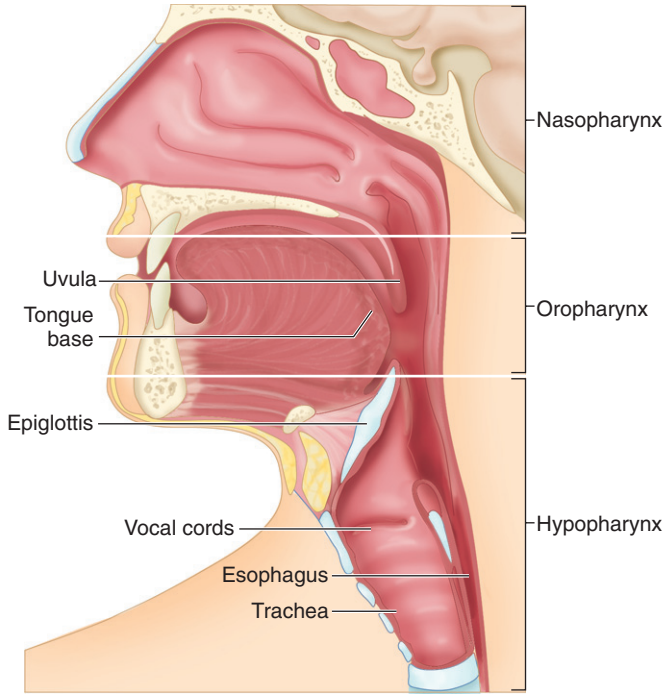

FIGURE 437-1. The pharynx (throat) is typically divided into three distinct anatomic regions (nasopharynx, oropharynx, and hypopharynx).

437 THROAT DISORDERS

THOMAS A. TAMI

The functions of deglutition, respiration, voice, and alimentation are influenced by disorders of the throat. Because the anatomy in this area is characterized by indistinct boundaries, symptoms are often difficult to ascribe to a specific anatomic area without a careful physical examination.

PATHOBIOLOGY

The pharynx is usually divided into three regions (Fig. 437-1). The *nasopharynx,* which is the region of the pharynx located above the soft palate and uvula, is usually very difficult to visualize directly unless the examiner is adept at using small nasopharyngeal mirrors or is able to use a fiberoptic endoscope introduced through the nose. Anatomic structures in the nasopharynx include the adenoids, the openings of the eustachian tubes, and the posterior tips of the inferior turbinates of the nasal cavity.

The *oropharynx* is anatomically defined as the region beginning at the level of the soft palate and extending inferiorly to the tip of the epiglottis. This anatomic area includes the faucial tonsils, the base of the tongue, the lingual tonsils, the soft palate, the uvula, and part of the posterior pharyngeal wall.

The *hypopharynx* is the lower part of pharynx extending from the tip of the epiglottis above to the introitus of the esophagus (the cricopharyngeus muscle) below. This region includes the entire larynx (epiglottis, arytenoids, glottis or true vocal cords), the pyriform sinuses (pharyngeal folds lateral to the larynx), and the posterior pharyngeal wall. Although the tip of the epiglottis can occasionally be visualized by using a routine flashlight and tongue blade during a routine oral examination, this region can usually be clearly visualized only by using a laryngeal mirror or, more commonly, a fiberoptic nasopharyngoscope.

DISEASE OF THE PHARYNX

Nasopharynx

CLINICAL MANIFESTATIONS

Typically, diseases occurring in the nasopharynx produce few symptoms until the process is well advanced and produces nasal obstruction (Chapter 434), epistaxis (Chapter 434), ear pain (Chapter 434), headache (Chapter 405), or cranial nerve abnormalities owing to extension to the skull base. Symptoms of postnasal drainage, including cough and sore throat, can be caused by acute or chronic sinusitis or by allergic or nonallergic rhinitis. Treatment is for the underlying cause (Chapter 434). Examination using fiberoptic technology can often easily establish the appropriate diagnosis, but magnetic resonance imaging (MRI) or computed tomography (CT) can also be helpful (Chapter 434), especially when extension outside the nasopharynx is suspected.

Nasopharyngeal carcinoma (Chapter 196), which is uncommon in Western populations but more common in Asian populations, particularly southern Chinese, is related to Epstein-Barr virus infection. Common presenting symptoms include nasal obstruction, unilateral or bilateral serous otitis media, epistaxis, cervical lymph node enlargement, or cranial nerve neuropathy that often arises as diplopia.

Oropharynx

PHARYNGITIS

In the oropharynx, sore throat (pharyngitis) is the most common presenting symptom (Fig. 437-2), and tonsillitis is the most important cause. Although the faucial tonsils are occasionally the only site of infection, the lingual tonsils and the adenoids are also usually involved. The clinical evaluation must differentiate among viral pharyngitis, bacterial causes (usually streptococcus (Chapter 298), tonsillitis, peritonsillar abscess, and (rarely) acute epiglottitis (Table 437-1).

Antibiotic treatment is recommended in patients at reasonable risk for bacterial infection (Chapter 298). Penicillin (penicillin VK, 250 mg three times a day or 500 mg twice a day for 5 to 10 days) is usually chosen to treat acute bacterial pharyngitis, but cefuroxime axetil (250 mg twice a day for 5 to 10 days) is even more effective for primary treatment and can be very effective for persistent infection. For patients who are allergic to penicillin, azithromycin (500 mg/day for 3 days or a single dose of 2 g) is an alternative. Any of these regimens is reasonable for patients with a positive throat culture or rapid antigen test for group A streptococci (Chapter 298). However, azithromycin is not effective against *Fusobacterium necrophorum*, which can cause severe Lemierre's syndrome (see later). For very symptomatic sore throat, short-term corticosteroid therapy (e.g., one dose of 8 mg dexamethasone intramuscularly, or prednisone, 60 mg orally for 1 or 2 days) can reduce pain without the risk for infectious complications.

Infectious mononucleosis (Chapter 385) often produces disabling tonsillitis with impressive exudative tonsillar hypertrophy (Fig. 437-3). Corticosteroids (see earlier) are very effective during the acute phase of infectious mononucleosis, particularly for patients with potential airway obstruction related to tonsillar hypertrophy. Because this systemic viral disease can also

produce other medical problems, such as hepatitis and thrombocytopenia, these possibilities should be considered during the clinical evaluation.

Peritonsillar abscess can usually be diagnosed by physical examination (Fig. 437-4). A peritonsillar abscess can usually be managed in an outpatient setting using surgical or needle drainage by an ear, nose, and throat specialist and oral antibiotics, such as amoxicillin plus metronidazole or clindamycin or amoxicillin clavulanate.

By comparison, a deep neck abscess is a more serious condition because of its anatomic access to the fascial planes of the neck and chest. These patients usually present in a more toxic condition and often have swelling of the external neck, trismus, or torticollis and, occasionally, a compromised airway. These infections must be recognized immediately, often using imaging techniques, and managed aggressively, usually by external incision and drainage as well as with intravenous broad-spectrum antibiotic coverage of aerobic and anaerobic bacteria (e.g., clindamycin, 600 mg intravenously every 8 hours; ampicillin-sulbactam, 3 g every 6 hours; or penicillin G, 2 million units every 4 hours plus metronidazole 500 mg every 6 hours).

An uncommon yet quite serious complication that can result from severe infections of the pharynx is septic thrombophlebitis of the internal jugular vein (Lemierre's syndrome). Patients typically have an underlying peritonsillar abscess and present with persistent fever, difficulty swallowing, neck pain, and a neck mass. Patients may develop bacteremia and septic pulmonary emboli. The diagnosis is best made by a CT. This potentially life-threatening condition, which is almost always associated with anaerobic infection, especially with *F. necrophorum*, can sometimes extend into the intrathoracic vasculature. Treatment usually consists of antimicrobial therapy including anaerobic therapy (with either clindamycin 600 mg every 8 hours or metronidazole 500 mg every 6 hours), anticoagulation, and occasionally surgery, especially when it is associated with vascular extension or pulmonary embolization. Mortality rates can be as high as 5%.

TONSILS

Patients who have deep crypts and crevices in the tonsils can accumulate debris, such as food or sloughed mucosa, within these crypts, which provide an ideal environment for the growth of bacteria, especially anaerobes. These patients typically complain of whitish or yellow pieces of semisolid debris emanating from their tonsils. These tonsilloliths often have a foul odor and taste, and they sometimes can be associated with halitosis. Occasionally, these patients also complain of chronic sore throat owing to chronic secondary infections. Treatment usually consists of maintaining good tonsillar hygiene with frequent throat gargling and occasionally manually expressing this debris from the tonsil. If patients have symptomatic chronic, recurrent tonsillitis, adenotonsillectomy can modestly reduce the recurrence rate.■

APHTHOUS STOMATITIS

Aphthous stomatitis, typically encountered in the oral cavity (Chapter 433), can also occur in the oropharynx. The spectrum of causes and their treatment is similar to that for oral stomatitis.

THRUSH

Oral and pharyngeal candidiasis (thrush) is usually easily recognized by its typical "cottage cheese" exudative appearance. However, in the atrophic form of thrush, the inflammatory mucositis can be present without typical exudates. Treatment with either topical (clotrimazole or nystatin) or systemic (fluconazole) agents usually results in immediate and dramatic symptomatic improvement (Chapter 346). Underlying medical conditions commonly associated with thrush include diabetes, immune deficiency, malignancies, prolonged use of antibiotics, and xerostomia (dry mouth).

TUMORS

The most common benign tumor of the oropharynx is the squamous papilloma, which is associated with human papillomavirus (Chapter 381) infection. These small, benign, usually pedunculated tumors often have a predilection for the soft palate and uvula (Fig. 437-5). In some circumstances, these can become widely disseminated within the mouth and pharynx. Although they are rarely symptomatic, removal is recommended when these produce undue concern on the part of the patient or the physician.

FIGURE 437-3. Mononucleosis can produce impressive symmetrical exudative tonsillitis as shown in this patient.

TABLE 437-1 CLINICAL DIFFERENTIATION OF COMMON CONDITIONS ARISING AS SORE THROAT

FEATURE	VIRAL PHARYNGITIS	BACTERIAL TONSILLITIS	PERITONSILLAR ABSCESS	EPIGLOTTITIS
Tonsillar enlargement	Usual	Rare	None	None
Tonsillar exudates	Occasional (mononucleosis)	Usual	Often	None
Tonsillar asymmetry	None	None	Usual	None
Trismus (inability to open jaw)	None	None	Usual	None
Cervical adenopathy	Occasional	Usual (tender)	Usual (tender)	None
Tender larynx	Rare	None	None	Usual

FIGURE 437-4. If the tonsils are inflamed and appear asymmetrical with unilateral palatal swelling and uvular deviation, a peritonsillar abscess should be suspected.

FIGURE 437-5. Benign squamous papilloma. A benign squamous papilloma usually arises as a solitary lesion of the oropharynx, usually on the palate or uvula, but occasionally, especially in immunocompromised patients, the papillomatosis can become widespread on the oral and oropharyngeal mucosal surfaces.

Hypopharynx

The hypopharynx is difficult to examine and assess. Nevertheless, when the presenting symptoms cannot be easily explained on the basis of the standard oral and oropharyngeal examination, conditions in the hypopharynx and larynx should be considered.

EPIGLOTTITIS

Epiglottitis (supraglottitis) is an uncommon problem but now is more common in adults than in children because of vaccination against *Haemophilus influenzae* in children (Chapter 308). The typical adult presenting with epiglottitis has a severe sore throat and odynophagia, often with fever and occasionally with a compromised airway, despite few or no findings on the oral or oropharyngeal examination. An examination of the larynx, preferably using a nasal fiberoptic endoscope, typically reveals swelling, erythema, and occasionally exudates of the epiglottis and other supraglottic structures. During the examination, palpation or manual movement of the larynx by external palpation produces significant pain. Patients with a confirmed diagnosis of epiglottitis require intravenous antibiotics (e.g., cefotaxime, 2 g every 6 hours, or ceftriaxone, 1 to 2 g/day, intravenously) and close observation because of the risk of developing a compromised airway. Low-dose corticosteroids (e.g., prednisone, 1 mg/kg, or dexamethasone, 0.15 mg/kg, given once) appear to be as beneficial as higher doses (e.g., dexamethasone, 0.6 mg/kg given once) for croup in children.[1]

HOARSENESS

The symptom of hoarseness invariably points to the larynx as the site of pathology. Benign lesions are most common, including vocal nodules (screamer's nodules), vocal cord cysts, vocal cord granulomas (usually resulting from intubation trauma or laryngopharyngeal reflux), and vocal cord papillomas. Malignancies must be suspected (Chapter 196), especially in patients with a strong smoking history.

Of the malignant tumors that can occur in the hypopharynx and larynx, squamous cell carcinoma is the most common and is usually associated with tobacco and ethanol use. Squamous cell carcinoma (Chapter 196) can occur on essentially any mucosal surface in the head and neck. Symptoms can range from mild sore throat to hoarseness, severe dysphagia, and odynophagia. Pain is often referred to the jaw or ear. Associated cervical lymph node enlargement is also common in advanced disease. Successful management depends on early detection by a careful examination of the entire upper aerodigestive tract, biopsy with histopathologic examination, and aggressive treatment based on the clinical stage and site of the lesion. Symptoms of hoarseness or of odynophagia (Chapter 140), hemoptysis (Chapter 83), aspiration (Chapter 94), enlarging neck nodes (Chapters 171 and 196), and otherwise unexplained ear pain (Chapter 434), especially when present for more than 4 to 6 weeks, should be investigated carefully with a thorough head and neck examination, which must include either indirect or a direct laryngoscopy.

Neurologic conditions affecting the larynx include unilateral vocal cord paralysis, which produces a "breathy" voice because the vocal cords cannot meet in the midline. The mobile cord often compensates over several months by moving across the midline to meet the paralyzed cord, thereby improving the voice. However, when compensation is inadequate or when aspiration occurs, vocal cord medialization procedures can be considered.

Bilateral vocal cord paralysis, either iatrogenic owing to thyroid surgery or thoracic surgery or, on occasion, owing to the Arnold-Chiari malformation (Chapter 426), may not produce severe impairment of voice because the cords are often positioned very close to one another in the midline; however, airway obstruction, especially with exertion, can be severe. In spasmodic dysphonia (Chapter 415), central nervous system–mediated dystonia of the vocal cord musculature causes a strained and tight-sounding voice that worsens with continued use. Severely affected patients are often unable to maintain a voice beyond one or two words. Botulinum toxin injected directly into the vocalis muscle of the vocal cord can provide substantial symptomatic relief for up to 6 months.

DYSPHAGIA AND ESOPHAGEAL REFLUX

Dysphagia (Chapter 140) can have its origins in the hypopharynx, and the possibility of a mass lesion producing swallowing dysfunction must always be considered early in the diagnostic evaluation (see Hoarseness).

Symptoms of gastroesophageal reflux disease (GERD) may include intermittent hoarseness, chronic cough, postnasal drip, "globus" sensation, reactive airway disease, halitosis, and a brackish or acid taste in the back of the mouth and throat. Laryngoscopy typically reveals posterior laryngitis, with swollen and erythematous arytenoid cartilages, thickening of the vocal folds, interarytenoid edema, and thickening of the mucosa. When treatment aimed at nasal disorders (topical steroids, antihistamines, mucolytics, decongestants) fails to provide symptomatic relief, reflux disease should be suspected. Treatment is a therapeutic trial of a proton pump inhibitor (Chapter 140) for up to 3 months.

Spasm or thickening of the cricopharyngeus muscle, also known as the upper esophageal sphincter (Chapter 140), can cause poor pharyngeal emptying and occasionally cause spillage and penetration of secretions into the larynx with aspiration. This finding is common in patients with GERD and also seems to increase with age. Chronic cricopharyngeal spasm can result in the development of a diverticulum of the hypopharynx (Zenker's diverticulum; see Fig. 140-9 in Chapter 140). These diverticula, which can slowly enlarge, can also serve as a reservoir for lodged food, medication, or other ingested materials for hours. The hallmark of Zenker's diverticulum is regurgitation of undigested food up to 4 hours after a meal; when large or symptomatic, these diverticula can usually be managed surgically.

Progressive neurologic conditions such as multiple sclerosis (Chapter 419) or amyotrophic lateral sclerosis (Chapter 418) can arise as slowly progressive dysphagia owing to loss of coordination of the swallowing musculature. An acute stroke (Chapter 414) also can lead to impaired swallowing. Although these underlying neurologic conditions are not curable, attention to adequate alimentation and protection of the airway from aspiration are paramount. A careful evaluation by a swallowing therapist can provide invaluable management recommendations, including alterations of swallowing techniques, changes in food consistency, and timing of other interventions, such as gastrostomy tube feedings or even tracheostomy for airway management.

PRINCIPLES OF MEDICAL CONSULTATION

GERALD W. SMETANA

APPROACH TO MEDICAL CONSULTATION

A general medical or subspecialty medical physician may receive a request to perform a consultation for a variety of purposes. In some settings a single consultative encounter will be requested, or the consultant will determine that only one visit, either in the inpatient or in the outpatient setting, is necessary. More commonly, the approach will include one or more follow-up visits to meet the goals of the consultation from the perspectives of the requesting physician, patient, and consultant. The consultant generally assumes one of four roles: cognitive consultant, procedural consultant, comanager with shared care, or comanager with principal care. The consultant as a comanager continues to care for a component of the patient's needs in an ongoing fashion while being careful to coordinate this comanagement with the continuing role of the requesting physician. Finally, in some situations it may be most appropriate for the physician who initially requested the consultation no longer to play an active role in the care of the patient but rather to transfer ongoing care exclusively to the consultant.

From a practical perspective, consulting medical physicians, whether they are generalists or subspecialists, enter into the consultative mode in a relatively limited number of ways. Surgeons may request a preoperative medical consultation to assess operative risk and obtain recommendations regarding perioperative care (Chapter 439) or, after surgery, to seek help in managing specific postoperative complications or assisting in the patient's long-term management. Both general medical physicians and medical subspecialists appropriately seek help from a subspecialist with particular knowledge in problems outside their own area of expertise to reduce uncertainty. Sometimes these requests are for specific medical procedures, but requests often seek cognitive guidance as well. Finally, noninternists may seek medical consultation for reasons other than perioperative care. For example, a psychiatrist may request a consultation to help determine whether the somatic symptoms of a particular patient represent important medical conditions (Chapter 442). In the peripartum setting, specific complications of pregnancy may require sophisticated medical consultation (Chapter 247).

Each of these settings raises different challenges for the medical consultant. In all settings, however, a number of general principles apply and can improve the effectiveness of consultations.

SETTING-SPECIFIC CONSULTATIVE ISSUES

An effective consultant must recognize the setting in which the consultation is requested and possess the required content knowledge. Distressingly, a number of studies have demonstrated that the requesting physician and the consultant often have different views on the reasons why a consultation was requested, and this initial disconnection, if present, will doom any medical consultation.

Preoperative Surgical Consultation

In the preoperative setting, the medical consultant should not "clear" a patient for surgery and must avoid the temptation to do so even if asked. Clearance may incorrectly imply that the procedure has no risk or that the medical consultant will take responsibility for having misled the patient and surgeon. Instead, the medical consultant should help determine the inherent risk associated with the proposed procedure for the particular patient, whether the patient is in the best possible condition for surgery, and whether any generic or patient-specific interventions would reduce the risk (Chapter 439). Effective consultation also requires a specialized knowledge base, whether the consultation is focusing on a particular organ system or on overall perioperative risk (Chapter 439).

Postoperative Surgical Consultation

Surgeons typically request a postoperative medical consultation when a complication has developed that is beyond their area of expertise. These problems are commonly urgent, so the goal is expeditious consultation and prompt intervention. Management of these problems does not usually differ from that used for medical patients in nonoperative settings. Another reason for a postoperative consultation is to obtain assistance in post-hospitalization care or to facilitate seamless discharge planning. Consultants should aid in the transition to the outpatient or long-term care setting by taking primary or consultative roles as appropriate.

Medical-Medical Consultations

Cross-consultations between medical subspecialists or between a subspecialist and a generalist, in either direction, are quintessential examples of collaboration. For subspecialty consultations, the key is to provide the requested expertise without overstepping into the domain of the expertise of the requesting physician. A growing example of medical-medical consultation is the situation in which a hospitalist assumes principal responsibility for an inpatient admission and then returns the patient to the primary care physician after discharge from the hospital. In this consultative interaction, close communication is critical because primary responsibility for the patient's care has shifted from the outpatient medical physician to the inpatient physician. This transfer of responsibility is not dissimilar to that occurring when a patient is submitted to the care of a subspecialist for a procedure such as cardiac catheterization or gastrointestinal endoscopy. Similar issues also arise when a critically ill patient with a condition such as a complicated myocardial infarction (Chapter 73) or shock (Chapters 106, 107, and 108) is managed principally by an inpatient-oriented medical specialist and is then expected to return to the care of the primary physician after hospital discharge. However, a key difference is that the inpatient hospitalist physician, unlike the consulting subspecialist, will not typically have any ongoing comanagement role. Because of the higher risk for discontinuity, effective communication at the time of hospitalization, whenever key issues arise during hospitalization, and at the time of discharge is even more important in the inpatient hospitalist model than in the other settings in which subspecialists may take on more of a comanagement role. Effective and comprehensive "handoffs" at the time of hospital discharge improve continuity and reduce the potential for errors and medicolegal liability.

Rapid Response Teams

A recent quality improvement initiative has been the development of rapid response teams. In this model, a prespecified consultative team urgently sees sick, hospitalized patients when a "trigger" abnormality indicates potential impending serious complications. The activation triggers for rapid response teams have varied somewhat among institutions, but there is substantial agreement on what constitutes an appropriate trigger (Table 438-1). Although implementation of these teams has not consistently reduced hospital mortality, most trials have shown a reduction in unplanned intensive care unit (ICU) transfers and in hospital length of stay. For example, in a trial of 5391 patients at a single academic medical center, patients randomly assigned to a rapid response team had a shorter length of stay, fewer unplanned ICU transfers, and lower mortality in patients with unplanned ICU transfers.■ Other studies have shown a greater impact on unplanned ICU transfers and a reduction in hospital cardiac arrest rates.

This novel consultative strategy crosses specialties and may include general internal medicine, hospital medicine, and critical care physicians, as well as respiratory therapists and ICU nurses. When an emergency consultation is generated by a trigger event, the consultant's relationship is primarily with the patient rather than with the referring physician.

Consultations for Special Populations

When consulting for psychiatrists or in the peripartum period, the consultant requires special expertise to understand the different expressions of signs and symptoms in specific populations, as well as how and when to modify typical medical recommendations because of special circumstances (Chapters 247 and 442). Although these consultations occasionally result in long-term comanagement, more commonly they revolve around the resolution of an isolated problem. In addition, the medical consultant should not make assumptions about the requesting physician's knowledge base regarding the specific medical issues that generate the consultation. The written report and verbal communications should be comprehensive and commonly include more basic medical content and specific recommendations than may be typical of a consultation for a medical subspecialist.

Subspecialty consultations requested by primary care physicians may be for advice, a technical procedure, or ongoing comanagement (Table 438-2).

TABLE 438-1 TRIGGERS: CRITERIA FOR MOBILIZING AN IN-HOSPITAL RAPID RESPONSE SERVICE

VITAL SIGNS	
	Heart rate • heart rate <40/min, especially if symptoms • heart rate >140/min Blood pressure • systolic blood pressure <90 mm Hg or >30-40 mm Hg below patient's usual stable blood pressure • systolic blood pressure >200 mm Hg for >30 min • diastolic blood pressure >110 mm Hg with symptoms Respiratory rate • respiratory rate <8/min or >35/min • new onset of marked dyspnea, compromised airway, cyanosis Oxygenation • O_2 saturation <85% for >5 min (except patients with chronic severe hypoxemia) • need for 100% supplemental O_2 or a non-rebreathing O_2 mask Temperature • fever >39°C or associated with acute decompensation
NEUROLOGIC STATUS	
	• acute change in mental status • new focal findings • prolonged or repeated seizures • ≥2 point decline in Glasgow coma scale score
GENERAL STATUS	
	• uncontrollable bleeding • decreased urine output to <50 mL over 4 hours

Based on criteria of the Joint Commission on Accreditation of Healthcare Organizations and on other sources.

TABLE 438-2 REASONS TO CONSIDER A SUBSPECIALTY CONSULTATION

To provide ongoing co-management: become a partner in in-patient care • for an acute, unstable problem • for a chronic condition
To perform a procedure (or advise on whether to perform it) • diagnostic • therapeutic
To provide one-time or periodic advice • diagnostic guidance • therapeutic guidance • reassurance • medico-legal issues

Consultations for general practitioners or family physicians generally follow the same guidelines as those for general internists. However, because both the training and ongoing practices of such physicians may or may not include the same spectrum and complexity of disease encountered by typical general internists, the subspecialty consultant must use judgment regarding both the initial consultation and the advisability of ongoing comanagement.

STRATEGIES FOR EFFECTIVE CONSULTATION

It is critical that requesting and consulting physicians agree about the reason for the consultative request. For example, the nature of a preoperative medical consultant's evaluation would differ substantially if the request were (1) routine, (2) for advice on perioperative insulin management in a patient with type 1 diabetes, or (3) to assist in determining the risks and benefits of proceeding to vascular surgery in a high-risk patient with coronary artery disease and a previous stroke. Effective communication at the time of the request will improve the value of the consultation and clarify the question. When there is doubt regarding the reason for the consultation, the consultant should speak directly to the referring physician before completing the evaluation of the patient.

Common reasons for medical consultation include assessment of perioperative risk; interpretation of a laboratory abnormality; help in performing a procedure, in obtaining advice, or in selecting therapy; and aid in providing long-term care. Prophylactic strategies (venous thromboembolism, endocarditis, and surgical site infection) infrequently generate requests for medical consultation because they are commonly standardized to conform to practice guidelines at individual institutions.

Determining the question will also help narrow the scope of the consultant's advice and minimize the number of recommendations. This focus is especially important inasmuch as evidence indicates that adherence by the requesting physician to any of the recommendations made by the consultant is higher for consultations with fewer recommendations. Another strategy to minimize the number of recommendations is to restrict advice to pertinent issues at the time, preferably in order of their importance. For example, a consultant who is asked to aid in the care of a critically ill pregnant patient with HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) (Chapters 163 and 247) should not also make recommendations regarding the value of cigarette cessation (Chapter 31), even though this issue will be pertinent after the mother and child have survived the acute event.

Requesting physicians are also more likely to adhere to recommendations when the patient is sicker, when the consultation is performed promptly, when advice is given to institute specific therapy rather than perform more diagnostic testing, when the consultant writes frequent follow-up notes, and when computerized order entry support systems are used to convey recommendations. When giving advice about medications, consultants should indicate specific doses and duration of treatment. If a recommendation is likely to be controversial (e.g., postpone surgery), it is always preferable to speak directly to the requesting physician before writing a consultation note in the hope that direct conversation will provide an opportunity to develop a consensus that may then be reflected in the formal consultation note. In one study of 323 physicians, the three elements of greatest perceived importance for a high-quality consultation request were to frame the question, to indicate clearly whom to call with the response, and to establish urgency.

Consultants should be careful to restrict their advice to their particular area of expertise. For example, unless a particular antipsychotic medication is contraindicated because of a medical issue (Chapter 442), it is wisest to defer decision making regarding psychiatric management to the psychiatrist. A strongly worded consultation note that advises against a particular strategy will put another physician in a difficult medicolegal position if it differs from the physician's usual or recommended practice.

Salerno and colleagues have proposed modifications of Goldman's original "Ten Commandments" for effective consultations (Table 438-3). These recommendations serve as a helpful guide for consultants to improve adherence to their advice and, as a result, improve patient outcomes.

SPECIAL CONSULTATIVE SITUATIONS

Curbside Consultation

Informal consultations are commonly termed "curbside" consultations. In the current era, ready access to online medical references may potentially reduce curbside requests. Consultants in "cognitive" specialties such as infectious diseases, rheumatology, and endocrinology provide a disproportionate amount of informal (as compared with formal) consultations. Informal consultations may occur by telephone, by e-mail, or in person. Curbside consultation is ingrained into the fabric of medical care.

Both generalists and specialists participate in an average of three to four curbside consultations per week. These consultations commonly involve questions about diagnostic tests, treatment plans, and the potential value of a formal consultation (which follows approximately a third of curbside consultations) in the future. To be effective, curbside consultations should be brief, involve a single question, and require no direct examination of the patient or medical records.

An important limitation of curbside consultations is that the consultant must rely on limited, secondhand information from the requesting physician rather than primary data from direct evaluation of the patient. Consultants report that such indirect information is often inaccurate on subsequent formal consultation. This reality, along with lack of financial compensation, leads to a greater degree of dissatisfaction with the curbside process by consultants than by requesting physicians. Salaried consultants may view a request for a curbside consultation more favorably than might those whose livelihood depends on a fee-for-service model of care.

Although requesting physicians may perceive reduced medicolegal risk when they obtain and even document a curbside consultation, consultants may fear the risk of malpractice liability themselves when offering such advice.

However, courts have consistently found that curbside consultants have no liability because no direct physician-patient relationship exists. Rather, the relationship is only between the requesting and consulting physicians.

Mandatory Consultations

In some situations, mandatory consultations may help enforce a standard of care. For example, mandatory inpatient infectious disease consultations, as part of an antimicrobial stewardship program, can improve the rational use of antimicrobial agents in the hospital and after discharge. Similarly, instituting routine consultation for patients with certain sentinel conditions, such as diabetes, may improve outcomes.

Comanagement

A consultation that begins with an initial encounter or a limited number of follow-up visits may evolve into ongoing comanagement. In such an arrangement, the physician initially serving in a consultative role becomes at least coequal to the requesting physician in the provision of ongoing care. In some situations, the consultant may actually become the primary physician. This arrangement is obvious in situations in which the consultation was requested specifically for the provision of ongoing care. Other examples include situations in which an oncologist assumes principal care of a patient with a malignancy or a nephrologist assumes principal care of a patient with end-stage renal disease who is being maintained on dialysis. In some of these situations, a general internist who initially requested the consultation may now become the consultant and provide advice on preventive care and occasional help with intercurrent medical problems.

Comanagement is also increasingly common in the hospital setting. Medical consultants may become comanagers of postoperative surgical patients, with a potential for improving outcomes. In one randomized trial of perioperative patients, formal comanagement, in which a medical physician took responsibility for managing medical problems rather than acting in a consultative role, reduced postoperative complications; in addition, both nurses and surgeons preferred this model.■ Similar benefit has been demonstrated in a study of comanagement for elderly patients with hip fractures. In some institutions, comanagement for orthopedic or other surgical patients has become routine and does not require a specific request for consultation.

In some settings the outpatient primary care physician may retain a comanagement role even as a cardiologist cares for a patient with acute myocardial infarction, a pulmonologist cares for a patient in the ICU, a hospitalist cares for a patient in the general medical setting, or a noninternist addresses a specific problem.

TABLE 438-3 GUIDELINES TO HELP MAKE CONSULTATIONS EFFECTIVE

Determine whether the goal is to obtain advice (and, if so, specifically for what) or to aid in ongoing co-management (see Table 438-2).
Understand the urgency of the consultation, so the consultation will be performed on a timely basis that meets the needs of the requesting physician and patient.
Perform a focused but careful history and physical examination—do not rely on information gathered by others.
Do not re-hash information in an overly detailed note—emphasize the key issue(s) your evaluation reinforced or discovered.
Be sure your recommendations are clearly listed and appropriately detailed—for example, indicate specific drugs, doses, and durations.
Limit the number of total number of recommendations in order to improve adherence.
Indicate how to monitor the effectiveness of your recommendations, as well as how to contact you urgently if problems arise.
Adjust your involvement (advice vs. co-management) as appropriate, in concert with the requesting physician.
Serve as a peer—teach as appropriate, but also seek to learn.
Remember that personal contact with the requesting physician, even if very brief, may be far more helpful than the best of written notes.
Do not disappear—follow the patient as frequently as appropriate, in coordination with the requesting physician.

For a more complete discussion of this topic, see Goldman L, Lee T, Rudd P. Ten commandments for effective consultations. *Arch Intern Med.* 1983;143:1753-1755 and Salerno SM, Hurst FP, Halvorson S, et al. Principles of effective consultation: an update for the 21st-century consultant. *Arch Intern Med.* 2007;167:271-275.

RESPONSIBILITIES OF THE CONSULTANT

The consultant is responsible to two parties: the patient and the referring physician. A paternalistic approach is not desirable. The consultant should not limit communication to just the referring physician and must not withhold discussion and recommendations from the patient. However, the consultant should not usurp the role of the referring physician, who remains responsible for assembling information and advice from varied sources, as well as for developing an integrated plan with the patient. For example, in the preoperative setting, the consultant should not express a final opinion regarding the suitability of proceeding to surgery without first discussing all relevant considerations with the referring surgeon. In the trilateral deliberative model, the patient, referring physician, and consultant each have responsibilities and constraints inherent in their relationships (Fig. 438-1). Above all, the role of the consultant is to improve patient care and outcomes.

IMPACT OF CONSULTATIONS ON PATIENT OUTCOME

Few studies have investigated the impact of medical consultations on outcomes. In one study, investigators randomly assigned 355 patients whose surgeons had requested a preoperative consultation to either an outpatient medical consultation or usual care (inpatient consultation at the discretion

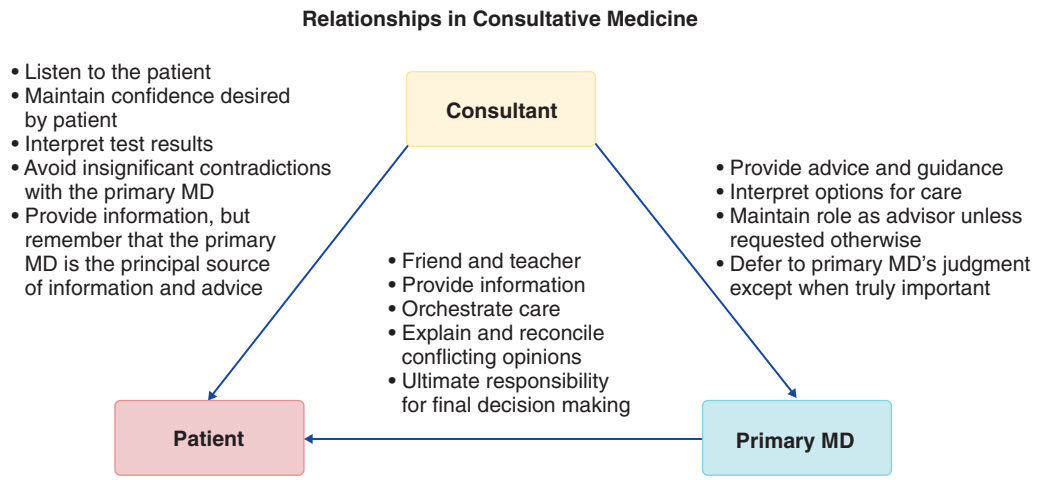

FIGURE 438-1. Consultative relationships. The consultant must execute his or her duty to the patient while acknowledging and hopefully conforming to the collegial professional model of advising the primary physician. If, however, the patient's safety or welfare is at stake, the consultant's duty is to be sure that the patient's needs always take precedence. (Based on Emanuel LL, Richter J. The consultant and the patient-physician relationship. A trilateral deliberative model. *Arch Intern Med.* 1994;154:1785-1790, and other sources.)

of the surgeon). Length of stay did not differ between the two groups, but there were fewer unnecessary admissions (those that did not result in surgery) in the outpatient consultation group. Other reports indicate that anywhere from 5 to 50% of preoperative medical consultations result in changes in patient management.

PREOPERATIVE EVALUATION

STEVEN L. COHN

PREOPERATIVE EVALUATION

Each year in the United States, more than 25 million inpatient surgical procedures and an additional 25 million outpatient procedures are performed. Although more than one third of these surgical patients are older than 65 years, overall morbidity and mortality are relatively low, in part because of modern anesthetic and surgical techniques. A crucial aspect of safety is careful preoperative evaluation of the patient, not only by the surgeon and anesthesiologist but also, in many instances, by a general medical consultant or medical subspecialist.

Operative Risk Assessment

The components of perioperative risk include those related to the patient, procedure, provider, and anesthesia. Anesthetic risk is low, with mortality less than 0.03% in a normal healthy patient—American Society of Anesthesiology (ASA) class 1—but increasing to 0.2% in ASA class 2 (mild systemic disease), 1.2% in class 3 (severe systemic disease), 8% in class 4 (severe systemic disease that is a constant threat to life), and 34% in class 5 (a moribund patient not expected to survive for 24 hours without surgery). Meta-analysis suggests that when feasible, neuraxial (spinal or epidural) anesthesia may reduce postoperative complications compared with general anesthesia (Chapter 440), but decisions regarding the anesthetic technique should be the responsibility of the anesthesiologist and not be part of the preoperative medical consultation. With respect to the provider, data support a "learning curve," with better outcomes when procedures are performed by more experienced, higher-volume surgeons.

General Risk Assessment

History and Physical Examination

The medical history and physical examination are the most important components in assessing a patient's risk for surgery. The consultation should focus on pertinent medical problems, particularly cardiopulmonary symptoms and diseases that are associated with risk and are likely to influence perioperative management (Chapter 438). The importance of the past surgical history is to determine whether the patient was able to undergo major surgery in the recent past or had any perioperative medical or anesthetic-related complications that could occur again. The social history should assess and quantify the amount, duration, and last use of tobacco, alcohol, or illicit substances. It is important to document allergies to medications, foods, and latex as well as to obtain an accurate list of the patient's current prescription and over-the-counter medications, including doses and adherence. The family history is relevant primarily for any genetically associated complications such as malignant hyperthermia. The review of systems should include the presence or absence of chest pain and dyspnea and the patient's exercise capacity. The physical examination must include the vital signs, assessment of the airway and respiratory status, cardiovascular examination, and documentation of any neurologic deficit.

Preoperative Tests

Screening preoperative test results in otherwise healthy individuals are usually normal and, even when abnormal, rarely affect management (generally <1%) (Table 439-1). Most significant abnormalities can be predicted from the clinical information obtained, which then guides selective testing based on the history, the physical findings, and the planned type of surgery and anesthesia. Most patients undergoing low-risk surgery with local anesthesia require no preoperative testing. Repeat testing should be avoided if recent (within 3 months) results were normal, unless the patient's condition or medications have changed.

Perioperative Medications

Decisions regarding whether to continue a medication perioperatively should consider the drug's pharmacokinetics (Chapter 28) as well as its effects on the primary disease and perioperative risk, including potential interactions with anesthetic agents. Some medications are essential to continue (e.g., cardiac medications and corticosteroids), whereas others must be discontinued (e.g., oral hypoglycemic agents) or have their dose altered (e.g., insulin and anticoagulants). Still other medications should be started prophylactically to minimize perioperative risk (e.g., anticoagulants for prophylaxis against venous thromboembolism [Chapter 81] and antibiotic prophylaxis for surgical site infection or endocarditis [Chapter 76]). Data are often lacking or conflicting. Table 439-2 briefly summarizes "consensus" perioperative recommendations for the major classes of drugs.

Cardiac Risk Assessment

A significant proportion of patients who undergo surgery have either known coronary artery disease or risk factors for it, and postoperative cardiac complications are second only to direct surgical complications as a cause of perioperative mortality. The goal is to risk-stratify patients clinically and to determine whether additional testing, new medications, or cardiac interventions will be beneficial.

History and Physical Examination

Important information includes any history of previous cardiac disease (myocardial infarction [MI], angina, heart failure, arrhythmias, valvular disease), cardiac interventions (coronary artery bypass grafting, percutaneous coronary intervention), cardiac evaluation (noninvasive testing, angiography), risk factors (hypertension, diabetes mellitus, dyslipidemia, cigarette smoking), and associated diseases (peripheral arterial disease, stroke, chronic kidney disease, and chronic obstructive pulmonary disease [COPD]). Current status regarding chest pain or dyspnea, functional capacity, and medications should be assessed. The physical examination serves to confirm findings in the history as well as to assess severity and control of the disease (e.g., heart failure, hypertension, valvar disease). The preoperative electrocardiogram rarely changes management unless it demonstrates evidence of a recent or silent MI, but it is often useful as a baseline against which to compare postoperative tracings.

Cardiac Risk Indices

Over the years, a number of risk indices have been proposed to assist in preoperative cardiac evaluation. The most current of these, the revised cardiac risk index (RCRI; Table 439-3), was developed during the evaluation of several thousand patients, was validated in thousands more, and has been incorporated into the consensus guidelines developed by the American College of Cardiology and the American Heart Association. These guidelines, which are updated periodically, use a stepwise strategy based on clinical risk factors, surgery-specific risk, and exercise capacity, combined with a systematic approach to perioperative testing and treatment in patients with known or suspected cardiac disease (Fig. 439-1). Preoperative levels of brain

TABLE 439-1 RECOMMENDATIONS FOR PREOPERATIVE LABORATORY TESTING

TEST	% ABNORMAL	% INFLUENCING MANAGEMENT	INDICATIONS
Hemoglobin	1.8	0.1	Expected major blood loss, symptoms of anemia, chronic kidney disease
White blood count	0.7	0.0	Suspected infection, myeloproliferative disorder, myelotoxic medications
Platelet count	0.9	0.02	Bleeding diathesis, myeloproliferative disorder, myelotoxic medications
Prothrombin time	0.3	0.0	Bleeding diathesis, liver disease, malnutrition, antibiotic use, anticoagulants
Partial thromboplastin time	6.5	0.1	Bleeding diathesis, anticoagulant use
Electrolytes	12.7	1.8	Renal disease, medications affecting electrolytes (e.g., diuretics, digoxin, ACE inhibitor, ARBs)
Glucose	9.3	0.5	Known DM, steroids, morbid obesity
Renal function	8.2	2.6	Renal disease, DM, HTN, major surgery, older age, medications affecting renal function
Liver function tests	0.4	0.1	Known liver disease, albumin level if at risk for needing postoperative parenteral nutrition
Urinalysis	19.1	1.4	No indication unless GU symptoms or instrumentation planned
Electrocardiogram (<50 years old)	29.6 (19.7)	2.6	Age >40 yr in men or >50 yr in women or symptoms/signs of or previous known diagnosis of cardiac disease, DM, or HTN
Chest radiograph (<50 years old)	21.2 (4.9)	3.0	Age >50 yr undergoing major upper abdominal or thoracic surgery or symptoms/signs or previous known diagnosis of cardiac or pulmonary disease

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; DM = diabetes mellitus; GU = genitourinary; HTN = hypertension.

TABLE 439-2 PERIOPERATIVE MANAGEMENT OF MEDICATIONS

MEDICATION CLASS	RECOMMENDATION
Anticoagulants (heparins, warfarin)*	Continue for minor surgery Discontinue at an appropriate interval before major surgery Consider bridging anticoagulation for patients at high risk for interim thrombosis (see Chapter 37)
Antiplatelet drugs	Continue for minor surgery Discontinue clopidogrel at least 5 days before surgery and prasugrel at least 7 days before surgery If discontinuing aspirin, do so at least 5-7 days before surgery
Cardiovascular medications	Continue most agents Consider starting β-blockers in patients at high risk for perioperative cardiac morbidity (vascular or high-risk surgery) Withhold diuretics on the morning of surgery, especially if signs of volume depletion are present Stop tamsulosin before cataract surgery (floppy iris syndrome)
Lipid-lowering agents	Continue "statins" Discontinue other agents
Pulmonary agents	Continue
Gastrointestinal agents	Continue
Diabetic agents (see text)	Withhold oral hypoglycemic agents on the morning of surgery; restart when the patient resumes eating For type 1 diabetes, continue some form of insulin (long acting or intravenous) at all times For type 2 diabetes, decrease the dose of morning intermediate insulin
Thyroid agents (hypothyroidism and hyperthyroidism) (see text)	Continue thyroid replacement Continue antithyroid medication and postpone surgery until the hyperthyroidism is controlled
Oral contraceptives, hormone replacement, and SERMs	May discontinue 3 weeks before surgery only in patients at high risk for perioperative venous thromboembolism; otherwise continue
Corticosteroids (see text)	Continue chronic corticosteroids; increase the dosage to account for surgical stress
Psychotropic agents	Continue SSRIs but consider withholding them several weeks before CNS surgery Continue tricyclic antidepressants, benzodiazepines, lithium, and antipsychotics Usually discontinue MAOIs 10-14 days before surgery
Chronic opioids	Continue; substitute equianalgesic or higher doses for surgical pain
Rheumatologic agents	Continue methotrexate Discontinue other DMARDs and anticytokines Continue hypouricemic agents
Neurologic agents	Continue antiseizure medications Consider withholding antiparkinsonian agents briefly Continue agents for myasthenia gravis
Herbal agents	Discontinue all agents

*See also Table 439-8 for more detail.
CNS = central nervous system; DMARD = disease-modifying antirheumatic drug; MAOI = monoamine oxidase inhibitor; SERM = selective estrogen receptor modulator; SSRI = selective serotonin reuptake inhibitor.
Adapted from Cohn SL, Macpherson DS. Perioperative medication management. In: Cohn SL, Smetana GW, Weed HG, eds. *Perioperative Medicine: Just the Facts*. New York: McGraw-Hill, 2006.

natriuretic peptide (BNP) are independent predictors of postoperative cardiac complications, although the definition of an abnormal value has varied among studies. The emphasis of the new guideline is to minimize cardiac testing unless the results are likely to alter management.

Noninvasive Tests

A resting echocardiogram (Chapter 55) is indicated to evaluate valvular heart disease in patients with clinically suspicious murmurs and to evaluate left ventricular function in patients with heart failure. Other than for the assessment of aortic stenosis (see later), resting echocardiography is not a reliable predictor of perioperative cardiac events.

Exercise testing (with or without imaging) is preferred to pharmacologic stress testing because it assesses functional capacity (see Table 50-3 in Chapter 50), but its use is often limited by a patient's inability to achieve the target heart rate. Furthermore, patients with adequate exercise capacity by history rarely require preoperative stress testing.

Pharmacologic Stress Testing

Pharmacologic stress testing (either dipyridamole or adenosine with nuclear imaging [Chapters 56 and 71] or dobutamine echocardiography [Chapters 55 and 71]) is indicated when a patient cannot perform adequate exercise (see Table 71-6 and Fig. 71-3 in Chapter 71). Both tests have equivalent sensitivity for predicting perioperative ischemic complications, whereas stress echocardiography has fewer false-positive results. Dipyridamole and adenosine can cause bronchospasm and are best avoided in patients with symptomatic or severe asthma or obstructive lung disease, but they are preferred in patients with left bundle branch block, in whom exercise or stress echocardiography is more likely to give false-positive results. Quantitatively, the number and extent of reperfusion defects or wall motion abnormalities correlate with the severity of disease, likelihood of complications, and need for further evaluation by angiography.

Patients whose clinical condition would warrant stress testing independent of planned surgery should have such testing before elective operations. Otherwise, stress testing is recommended only in patients who are undergoing high-risk surgery (Table 439-4) and have three or more clinical risk factors (Table 439-5; see Table 439-3). Evidence for stress testing in other situations is weak, but it may be considered on an individual basis in patients with one or two risk factors if the results are likely to change management.

TABLE 439-3 CLINICAL FACTORS IMPORTANT IN ASSESSING PERIOPERATIVE CARDIAC RISK

Revised cardiac risk index criteria*
Patients are at risk and may be candidates for perioperative β-blockers if they have
- **Ischemic heart disease** or at least two of the following:
- **Heart failure**† defined as S_3 or bilateral rales on physical examination or pulmonary edema on chest radiograph
- **Cerebrovascular disease** defined as history of transient ischemic attack or history of cerebrovascular accident
- **Insulin-dependent diabetes mellitus**
- **Chronic renal insufficiency** defined as baseline creatinine of 2.0 mg/dL or greater
- **High-risk surgery** defined as intrathoracic, intra-abdominal, or suprainguinal vascular surgery

Risk Reduction Strategies for Ischemic Heart Disease

Medical Therapy

Prophylactic β-blockers (e.g., atenolol or bisoprolol) decreased major postoperative cardiac events in small early studies of higher-risk patients, but a number of subsequent studies failed to show a significant benefit. In by far the largest trial of prophylactic perioperative β-blockers, a high dose of extended-release metoprolol, started hours before surgery, reduced perioperative MI, but at the expense of increasing strokes and overall mortality, in part owing to more hypotension and bradycardia.■ A meta-analysis confirmed the benefit of β-blockers in reducing perioperative MI and the side effect of increasing stroke, but found no statistically significant difference in overall mortality,■ and a review of trials in which bisoprolol was started well before surgery found no relationship with postoperative stroke.■ Until more evidence is available, it seems prudent to avoid starting β-blockers immediately before surgery and to avoid them in the settings of emergency surgery, prior cerebrovascular disease, or sepsis (Table 439-6). β-Blockers may benefit patients at high risk for MI but not for stroke and are more likely to be beneficial when started at a lower dose well in advance of surgery and titrated to a heart rate of 55 to 70 beats per minute.■ Various recommended regimens are listed in Table 439-7.

If a patient has contraindications to β-blockers (bronchospasm, bradyarrhythmia, acute heart failure, advanced heart block), an α_2-adrenergic agonist (i.e., a transdermal clonidine extended-release TTS-2 patch the night before, and 0.2 mg orally the night before and morning of surgery) may be an alternative choice based on limited data that such medications also reduce ischemia and possibly perioperative MI and death, especially in patients undergoing major vascular surgery.■ Limited data on prophylactic calcium antagonists or nitrates have not shown major benefits in preventing complications after noncardiac surgery.

Statins (Chapter 213) reduce endovascular inflammation and stabilize endothelial plaque. Although the manufacturers' package inserts have recommend discontinuing statins before surgery, current data suggest not only that they should be continued perioperatively but also that they should be started prophylactically before surgery in patients who meet criteria for their ongoing use (Chapter 213).■

Invasive Therapies

Prophylactic coronary revascularization in patients who have stable cardiac symptoms and no aortic stenosis and do not meet standard criteria for the procedure (Chapter 71) does not appear to reduce perioperative myocardial infarction, death within 30 days, or long-term mortality at an average of 2.7 years in patients who receive appropriate medical therapy.■ Preoperative coronary revascularization is indicated only if the patient meets the criteria for coronary angiography or revascularization independent of the need for surgery, but even then coronary revascularization based on the results of preoperative noninvasive testing has not been shown to improve perioperative outcomes.■

For bare metal stents, data suggest that surgery should be delayed for 4 to 6 weeks after stenting because of the risk for in-stent thrombosis when dual antiplatelet therapy with aspirin and clopidogrel is discontinued early or because of the alternative risk for bleeding if surgery is performed in patients receiving such antiplatelet therapy (Chapter 74). Similar concerns apply with drug-eluting stents, for which the guidelines currently recommend continuing uninterrupted dual antiplatelet therapy for a minimum of 12 months because of the risk for late stent thrombosis. For balloon angioplasty without stenting, a delay of 2 weeks is generally recommended. If antiplatelet therapy has to be discontinued, clopidogrel is usually discontinued 5 to 7 days before (and prasugrel is stopped 7 days before) the noncardiac procedure, and aspirin is continued, if possible. If aspirin also needs to be discontinued, it is usually stopped approximately 1 week before surgery.

Other Cardiovascular Diseases

Heart Failure

Heart failure, which is a major risk factor for surgery, requires treatment and optimization before surgery (Chapter 59). Routine use of *pulmonary artery catheters* does not reduce morbidity or mortality in patients undergoing elective noncardiac surgery.■ At present, there is no evidence that treatment to lower the BNP level or use of β-blockers will reduce postoperative complications in patients with heart failure.

Aortic Stenosis

Patients with *symptomatic aortic stenosis* who meet the criteria for valve replacement (Chapter 75) independent of their need for surgery should undergo the valve surgery before the noncardiac surgery. However, patients usually survive surgery with intensified care if they refuse valve replacement or time does not permit it. Balloon aortic valvuloplasty may be an option in severe cases. An asymptomatic aortic valve gradient higher than 25 to 30 mm Hg also carries an increased risk for perioperative complications but is an indication for more careful monitoring rather than valve surgery. Endocarditis prophylaxis is appropriate for patients with mechanical heart valves, previous endocarditis, or complex congenital heart disease undergoing invasive dental or upper respiratory procedures (Chapter 76).

Hypertension

Hypertension with blood pressure lower than 110 mm Hg diastolic or 180 mm Hg systolic without significant target organ damage does not increase the risk for major perioperative cardiac complications. Even when the preoperative diastolic blood pressure is higher, limited data suggest that surgery is safe after additional antihypertensive therapy.

Arrhythmias

Although patients with arrhythmias have increased perioperative risk, the risk is increased because the arrhythmias are usually markers of more serious

TABLE 439-6 RECOMMENDATIONS FOR PERIOPERATIVE β-BLOCKER THERAPY*

2009 RECOMMENDATIONS OF AMERICAN HEART ASSOCIATION/AMERICAN COLLEGE OF CARDIOLOGY (ACCF/AHA)	RECOMMENDATIONS OF EUROPEAN SOCIETY OF CARDIOLOGY
CLASS I	
1. β-Blockers should be continued in patients undergoing surgery who are receiving β-blockers for treatment of conditions with ACCF/AHA class I guideline indications for the drugs (level of evidence: C).	1. β-Blockers are recommended in patients who have known ischemic heart disease or myocardial ischemia according to preoperative stress testing (level of evidence: B). 2. β-Blockers are recommended in patients scheduled for high-risk surgery (level of evidence: B). 3. Continuation of β-blockers is recommended in patients previously treated with β-blockers because of ischemic heart disease, arrhythmias, or hypertension (level of evidence: C).
CLASS IIA	
1. β-Blockers titrated to heart rate and blood pressure are probably recommended for patients undergoing vascular surgery who are at high cardiac risk owing to coronary artery disease or the finding of cardiac ischemia on preoperative testing (level of evidence: B). 2. β-Blockers titrated to heart rate and blood pressure are reasonable for patients in whom preoperative assessment for vascular surgery identifies high cardiac risk, as defined by the presence of more than 1 clinical risk factor† (level of evidence: C). 3. β-Blockers titrated to heart rate and blood pressure are reasonable for patients in whom preoperative assessment identifies coronary artery disease or high cardiac risk, as defined by the presence of more than 1 clinical risk factor,† who are undergoing intermediate-risk surgery‡ (level of evidence: B).	1. β-Blockers should be considered for patients scheduled for intermediate-risk surgery (level of evidence: B). 2. Continuation in patients previously treated with β-blockers because of chronic heart failure with systolic dysfunction should be considered (level of evidence: C).
CLASS IIB	
1. The usefulness of β-blockers is uncertain for patients who are undergoing either intermediate-risk procedures or vascular surgery in whom preoperative assessment identifies a single clinical risk factor in the absence of coronary artery disease† (level of evidence: C). 2. The usefulness of β-blockers is uncertain in patients undergoing vascular surgery with no clinical risk factors† who are not currently taking β-blockers (level of evidence: B).	1. β-Blockers may be considered in patients scheduled for low-risk surgery with risk factor(s) (level of evidence: B).
CLASS III	
1. β-Blockers should not be given to patients undergoing surgery who have absolute contraindications to β-blockade (level of evidence: C). 2. Routine administration of high-dose β-blockers in the absence of dose titration is not useful and may be harmful in patients not currently taking β-blockers who are undergoing noncardiac surgery (level of evidence: B).	1. Perioperative high-dose β-blockers without titration are not recommended (level of evidence: A). 2. β-Blockers are not recommended in patients scheduled for low-risk surgery without risk factors (level of evidence: B).

*See Table 439-5 for definitions of class of recommendation and level of evidence.
†See Table 439-3.
‡See Table 439-4.
Reproduced from Poldermans D, Bax JJ, Boersma E, et al. Guidelines for pre-operative cardiac risk assessment and perioperative cardiac management in non-cardiac surgery. The Task Force for Preoperative Cardiac Risk Assessment and Perioperative Cardiac Management in Non-cardiac Surgery of the European Society of Cardiology (ESC) and endorsed by the European Society of Anaesthesiology (ESA). *Eur Heart J.* 2009;30:2769-2812.

heart disease or cause hemodynamic problems. Patients with tachyarrhythmias and bradyarrhythmias should generally be treated as in the nonoperative setting (Chapters 64 and 65), except for the special circumstance of anticoagulation in the perioperative setting (Chapter 37).

Pulmonary Risk Assessment

Postoperative pulmonary complications are as common as cardiac complications and are associated with significant morbidity and mortality. Major complications include respiratory failure (e.g., reintubation, prolonged mechanical ventilation), pneumonia, atelectasis requiring bronchoscopy, and to a lesser degree, bronchospasm or an exacerbation of COPD requiring treatment and prolonged length of stay. Many postoperative pulmonary complications are due to exaggerations of the usual postoperative changes in pulmonary function: decreased lung volumes, diaphragmatic dysfunction, ventilation-perfusion mismatches and shunting, hypoventilation, hypoxemia, and impaired defense mechanisms. Pulmonary risk factors can be divided into patient-related and procedure-related factors, the latter of which includes the type of surgery, anesthesia, and related factors.

Patient-Related Factors

COPD (Chapter 88) increases the risk for postoperative pulmonary complications approximately twofold, depending on its severity, whereas well-controlled *asthma* (Chapter 87) does not increase risk. Active cigarette smokers are at increased risk, mainly related to the number of pack years smoked; smoking cessation at least 4 to 8 weeks before surgery may reduce the risk. *Obstructive sleep apnea* (Chapter 100), typically associated with obesity, confers an increased risk for hypercapnia and hypoxemia, and obese patients are at increased risk for atelectasis. Advanced age, poor functional status, an altered mental state, and suppressed immune status from chronic steroid use, alcohol use, or diabetes may also increase the risk for postoperative pulmonary complications.

Procedure-Related Factors

The most important predictor of postoperative pulmonary complications is the type of surgery and proximity of the surgical incision to the diaphragm. Pulmonary function decreases by approximately 50% after intrathoracic surgery, upper abdominal procedures, and abdominal aortic aneurysm repair and does not fully return to normal for several weeks. Lower abdominal surgery is associated with a 25% decrease in pulmonary function. Laparoscopic procedures are usually associated with lower rates of postoperative pulmonary complications and shorter hospital stays than open procedures. Neuraxial anesthesia (epidural or spinal) may be associated with decreased risk when compared with general anesthesia, but the decision about which type of anesthesia to use is best left to the anesthesiologist. Emergency surgery, prolonged duration of anesthesia or surgery (>2 to 6 hours), and routine postoperative nasogastric tube use increase the risk for postoperative pulmonary complications.

Pulmonary Function Tests

In general, pulmonary function tests (Chapter 85) are no more predictive of pulmonary complications than is clinical risk assessment alone. Such testing may be more helpful in assessing risk for lung resection surgery when it can predict the function of the remaining lung mass. However, even a postoperative predicted forced expiratory volume in 1 second (FEV_1) of less than 800 mL for lung resection, which is thought to portend a very high risk for death or prolonged mechanical ventilation, is not an absolute

TABLE 439-7 PROTOCOLS FOR PROPHYLACTIC PERIOPERATIVE β-BLOCKERS*

GENERAL PRINCIPLES
Start β-blocker at least 1 week before surgery (if possible).
Titrate the dose to an ideal target heart rate of 55-70 beats/min.
Use half the dose if the heart rate is <65 beats/min, if systolic blood pressure is <120 mm Hg, or in a small elderly or frail patient.
Hold the dose if the heart rate is <55 beats/min or systolic blood pressure is <100 mm Hg.
Continue β-blocker postoperatively for at least 1-4 wk (or indefinitely if independent criteria such as known coronary artery disease, peripheral arterial disease, or hypertension are present). Taper the dose if discontinuing.
Before increasing the dose for postoperative tachycardia, evaluate the patient for other potential causes, including pain, bleeding, and sepsis (where β-blockers may be detrimental).
SPECIFIC DRUGS: ATENOLOL, BISOPROLOL, OR METOPROLOL
Preoperatively (recommended starting dose, then titrate to the target heart rate):
Atenolol: start at 25 mg orally daily
Bisoprolol: start at 5 mg orally daily at least 7 days before surgery
Metoprolol: start at 25-50 mg orally twice daily up to 30 days preoperatively
Day of surgery—continue the usual dose or increase the oral dose to control the heart rate or give additional intravenous (IV) doses (atenolol or metoprolol, 5-10 mg) as needed if unable to take orally. Esmolol can also be used (500-μg/kg IV loading dose over a 1-min period; then infuse at 50-200 μg/kg/min and titrate to the target heart rate)
Postoperatively—continue the usual preoperative dose:
Atenolol: 25-100 mg orally daily for at least 7 days
Bisoprolol: 2.5-5 mg orally daily for at least 30 days
Metoprolol: 25-100 mg orally twice daily for at least 14 days
Substitute IV atenolol or metoprolol (5-mg doses) as needed if unable to take medication orally

*See Table 439-6 for indications.

contraindication to surgery. Preoperative arterial blood gas evaluation is also of little benefit in predicting postoperative pulmonary complications.

Risk Reduction Strategies

Unfortunately, many of the risk factors for postoperative pulmonary complications cannot be modified. Inhaled bronchodilators (β-agonists and anticholinergics) and steroids can optimize the respiratory status of patients with COPD and asthma. Broad-spectrum antibiotics should be used to treat exacerbations caused by bacterial infection. Chest physiotherapy may be helpful. Smoking should be stopped at least 8 weeks before surgery, if possible.

Lung expansion maneuvers (either incentive spirometry or deep-breathing exercises) can significantly improve pulmonary function, minimize atelectasis, and reduce risk, especially for thoracic and upper abdominal surgery. Pain control (Chapter 29) improves pulmonary function by allowing deeper breathing. Epidural analgesia and patient-controlled intravenous analgesia reduce postoperative pulmonary complications and, when possible, are preferable to parenteral narcotics.

Endocrine Conditions

Diabetes Mellitus

The major risks associated with surgery in diabetic patients are cardiac complications and wound infections. Complications are probably related more to associated diseases and end-organ involvement (coronary artery disease, chronic kidney disease, and autonomic neuropathy) than to the glucose level itself. Significantly, elevated glucose levels may impair wound healing and interfere with leukocyte defense mechanisms. However, current recommendations suggest a glucose target level of 140 to 180 mg/dL rather than tight perioperative control.

Patients whose diabetes is controlled by diet require only perioperative glucose monitoring (fingersticks) with short-acting insulin coverage on an as-needed basis. Patients taking oral hypoglycemic agents (Chapter 237) should not take them on the morning of surgery (chlorpropamide should be stopped 2 to 3 days before and metformin preferably 1 day before) and should be monitored with sliding-scale insulin coverage as needed. Patients taking insulin are most often given half to two thirds of their usual intermediate-acting insulin on the morning of surgery and are then given short-acting insulin on a sliding scale and correction dose based on fingerstick monitoring (Chapter 236). Continuous intravenous insulin, which provides tighter glucose control but is associated with more episodes of hypoglycemia and requires a monitored setting, is typically used in patients undergoing cardiac surgery and in critically ill patients. There are no validated guidelines regarding the management of patients taking long-acting basal insulin (glargine). In general, it should be continued, but its dose may be reduced for ambulatory surgery or in patients with tight control. Regardless of the mode of treatment, frequent monitoring of the glucose level is critical.

Exogenous Corticosteroids and Adrenal Insufficiency

The stress of surgery activates the hypothalamic-pituitary-adrenal (HPA) axis, which in turn stimulates release of adrenocorticotropic hormone (ACTH) and subsequent secretion of cortisol (Chapter 234), but a patient who is taking exogenous corticosteroids may have suppression of the HPA axis and not be able to respond to this stress adequately. As a result, hypotension and shock may occur.

In general, a daily dose equivalent to 5 mg or less of prednisone (Chapter 234), alternate-day short-acting therapy, or corticosteroids given for less than 3 weeks do not cause clinically significant HPA suppression, so no supplemental therapy is indicated. Conversely, doses greater than 20 mg/day of prednisone for longer than 3 weeks usually suppress the HPA axis and warrant perioperative supplemental corticosteroids. In patients who are taking intermediate dosing regimens or who took large doses in the past year but are not taking corticosteroids or are taking lower doses now, the options are to perform an ACTH (cosyntropin) stimulation test, if time permits, and treat only patients with an inadequate response (Chapter 234) or to prescribe supplemental corticosteroids empirically.

When supplemental corticosteroids are appropriate, short-term therapy tailored to the level of expected stress can provide protection without adverse effects on wound healing and with only short-term problems with glucose intolerance and fluid retention. For minor procedures or local anesthesia, the recommended approach is to give the patient's usual dose before surgery without further supplementation. For moderate surgical stress (e.g., open cholecystectomy, lower extremity vascular surgery), a reasonable approach is 50 mg of hydrocortisone intravenously before surgery, followed by 25 mg every 8 hours for 1 to 2 days, and then the patient's usual dose. For major surgical stress, patients are typically given 75 to 100 mg of hydrocortisone intravenously before induction of anesthesia, followed by 50 mg every 8 hours for 1 to 3 days until the stressful period resolves, and then their usual dose.

Thyroid Disease

An inadequately treated or undiagnosed hyperthyroid patient is potentially at risk for thyroid storm postoperatively. Elective surgery should be postponed in patients who are symptomatic or have resting tachycardia until they are euthyroid. Treatment of a thyrotoxic patient undergoing urgent or emergency surgery includes a combination of β-blockers, antithyroid agents, and iodine to control the resting heart rate to less than 90 beats per minute, as well as prophylactic corticosteroid supplementation, as used for thyroid storm (Chapter 233).

Conversely, patients with mild to moderate hypothyroidism tolerate surgery reasonably well. Patients with markedly symptomatic hypothyroidism should be treated with oral levothyroxine (T_4) for several weeks before elective surgery. For emergency surgery, intravenous liothyronine (T_3) or T_4 (200 to 300 μg intravenously, then 50 to 100 μg/day) and supplemental corticosteroids (hydrocortisone, 100 mg intravenously, then 25 to 50 mg every 6 hours; also correct fluid and electrolyte abnormalities) should be given. Myxedema coma is a rare complication of surgery.

Liver Disease

Routine preoperative testing of liver function is not recommended, but elective surgery should be avoided in patients with acute viral or alcoholic hepatitis. Patients with stable mild chronic hepatitis tolerate surgery well.

Patients with alcoholic liver disease or cirrhosis are at risk for postoperative complications, including bleeding, infection, poor wound healing, and delirium. The severity of disease as assessed by Child-Turcotte-Pugh criteria and the MELD (Model for End-Stage Liver Disease) score (Chapter 157) can be used to estimate risk; the MELD score is thought to be more predictive of outcome. Aggressive treatment of coagulopathy, ascites, and encephalopathy is indicated before surgery.

TABLE 439-8 APPROACH TO ANTICOAGULATION IN THE PERIOPERATIVE PATIENT

Low thromboembolic risk/low bleeding risk
- Continue anticoagulant therapy with INR in therapeutic range.

Low thromboembolic risk/high bleeding risk
- Discontinue anticoagulant therapy 5 days before the procedure.
- Start LMWH prophylaxis once daily or UFH IV 1 day after acenocoumarol interruption and 2 days after warfarin interruption. Administer the last dose of LMWH at least 12 hr before the procedure or give UFH IV up to 4 hr before surgery.
- Resume LMWH or UFH at the preprocedural dose 1-2 days (at least 12 hr) before the procedure according to haemostatic status. Resume anticoagulant therapy 1 to 2 days after surgery at the preprocedural dose + 50% boost dose for 2 consecutive days according to the hemostatic status.
- LMWH or UFH is continued until the INR has returned to therapeutic levels.

High thromboembolic risk
- Discontinue anticoagulant therapy 5 days before the procedure.
- Start therapeutic LMWH twice daily or UFH IV 1 day after acenocoumarol interruption and 2 days after warfarin interruption. Administer the last dose of LMWH at least 12 hr before the procedure or give UFH IV up to 4 hr before surgery.
- Resume LMWH or UFH at the preprocedural dose 1-2 days (at least 12 hr) after the procedure according to hemostatic status. Resume anticoagulant therapy 1-2 days after surgery at the preprocedural dose + 50% boost dose for 2 consecutive days according to haemostatic status.
- LMWH or UFH is continued until the INR has returned to therapeutic levels.

LMWH = low-molecular-weight heparin; INR = international normalized ratio; IV = intravenous; UFH = unfractionated heparin.

Hematologic Problems

Anemia is associated with an increased risk for postoperative complications, but operative patients generally tolerate hemoglobin levels as low as 7 g/dL. Preoperative transfusion should not be triggered solely by the hemoglobin level but should also consider the expected blood loss from the surgical procedure and the patient's comorbid conditions. For patients with cardiopulmonary disease, however, a goal of 10 g/dL is typically recommended for major surgery.

Patients without a personal or family history of abnormal bleeding require no preoperative testing of coagulative function, but those with such a history should be evaluated. Ideally, the prothrombin time should be within 3 seconds of control (international normalized ratio <1.5), the partial thromboplastin time within 10 seconds of control, and the platelet count above a minimum of 50,000, depending on the type of surgery.

The approach to perioperative anticoagulation, both in terms of prevention of venous thromboembolism and for the management of a patient taking warfarin, aspirin, or other antithrombotic medications, is described elsewhere (Chapter 37). For patients already on anticoagulants, perioperative recommendations depend on the short-term risks for thromboembolism and bleeding (Table 439-8).

Renal Disorders

Chronic kidney disease is an independent risk factor for postoperative cardiovascular events and death. Patients with chronic kidney disease typically have other comorbid diseases and may also have fluid and electrolyte abnormalities, anemia, and bleeding diatheses, which should be treated and optimized before surgery. Patients maintained on dialysis should ideally undergo dialysis the day before surgery to optimize their volume status, prevent hyperkalemia, and minimize acute shifts in acid-base balance.

Neurologic Problems

The risk for a postoperative stroke in unselected patients after general surgery is less than 0.5%, but patients with a history of stroke, older patients, and those undergoing vascular surgery, especially carotid surgery, have higher risk. Patients with symptomatic carotid bruits require further investigation and possible intervention before elective surgery (Chapter 414). Patients who newly receive perioperative β-blockers are at increased risk for stroke, and the risk must be balanced against the protective effect of β-blockers for perioperative MI. However, there is no evidence that continuation of chronic β-blockade increases risk for postoperative stroke. There is no evidence to support preoperative intervention in patients with asymptomatic bruits before noncardiac surgery. The general recommendation is to delay elective surgery for at least 2 to 4 weeks after a stroke.

440

OVERVIEW OF ANESTHESIA

JEANINE P. WIENER-KRONISH AND LEE FLEISHER

In the United States, more than 40 million procedures, including outpatient procedures, that require an anesthetic are performed annually. With modern techniques, anesthesia causes or contributes to mortality in about 1 per 20,000 healthy patients. Perioperative mortality now more often relates to the patient's underlying diseases (Chapter 439).

PREOPERATIVE ASSESSMENT

Important aspects of preoperative risk assessment include the type of surgery to be performed, the patient's underlying medical condition, and the particular demands for anesthesia (Chapter 439). In addition, a number of other issues are relevant to management and anesthetic evaluation.

Airway Assessment

Assessment of the airway is always necessary even if regional anesthesia or monitored anesthesia care (local anesthesia with sedation) is planned because unexpected complications or compromise of airway reflexes may lead to an emergency need for ventilatory support. The laryngeal mask airway device allows many patients to be ventilated easily, but it is important to assess the ability to intubate the patient, as well as the ability to ventilate. Reasons for difficulty include airway pathology (e.g., tumors, previous surgery) or an abnormal anatomic relationship between the larynx and trachea. In many such patients, endotracheal intubation can be accomplished by placing the endotracheal tube via a fiberoptic bronchoscope through either the nose or mouth. If this approach is not successful, a surgical airway should be considered. The prevalence of difficult elective intubation in the operating room is about 6% in nonobese patients.

Malignant Hyperthermia

Malignant hyperthermia (Chapter 442) is characterized by acute hyperpyrexia developing during or immediately after general anesthesia. The channels that regulate the duration and amplitude of calcium efflux from the sarcoplasmic reticulum are the ryanodine receptors, which exist in three isoforms. Gain-of-function mutations affecting RyR1, the receptor expressed primarily in skeletal muscle, are present in 1 per 15,000 to 50,000 people and are associated with enhanced sensitivity to halothane and caffeine and with malignant hyperthermia and central core disease. More than 80 distinct mutations have been detected, and mutation of the adult skeletal muscle sodium channel SCN4A may also cause the syndrome. Patients with mutations predisposing to malignant hyperthermia function normally at resting conditions, but exposure to volatile anesthetics, including halothane, isoflurane, enflurane, desflurane, and sevoflurane, or exposure to a depolarizing muscle relaxant, succinylcholine, can precipitate life-threatening muscle contractures, increases in heart rate and body temperature, rhabdomyolysis, myoglobinuria, and metabolic acidosis. The mortality rate is 80% in untreated patients but about 5% with current treatment. Note that succinylcholine causes release of myoglobin from muscle in small amounts even in normal patients. Patients with malignant hyperthermia do not predictably respond to triggering agents, and some patients with malignant hyperthermia have had milder symptoms of malignant hyperthermia after the administration of nontriggering agents. Malignant hyperthermia now often presents differently, probably because of the decreased use of succinylcholine by anesthesiologists, diagnostic awareness of malignant hyperthermia by anesthesiologists, routine use of carbon dioxide monitors so that increases in end-expiratory carbon dioxide are detected quickly, and the availability of dantrolene. If malignant hyperthermia is suspected from a family history of adverse events with the administration of anesthetics or when a patient has a reaction suspicious for malignant hyperthermia, a muscle biopsy is usually performed for in vitro contracture testing, which evaluates the muscle contracture responses to caffeine or halothane. Genetic investigations are also recommended, but malignant hyperthermia cannot be excluded on the basis of genetic testing alone because of the diversity of mutations and genes that can be involved in this syndrome. The Malignant Hyperthermia Association of the United States (*www.mhaus.org*) is available for information to the public, and all medical personnel can get information 24 hours every day on the malignant hyperthermia hotline 1-800-MHHYPER (1-800-644-9737).

Dantrolene is the drug of choice to prevent and reverse the symptoms of malignant hyperthermia. Dantrolene decreases muscle sensitivity to caffeine, reduces calcium release from the sarcoplasmic reticulum, and produces some muscle weakness. Dantrolene comes in 20-mg bottles and must be dissolved in sterile water; the doses recommended are 2 mg/kg every 5 minutes intravenously until cardiac and respiratory symptoms stabilize, up to a total dose of 10 mg/kg; however, doses of 29 mg/kg have been reported. Side effects of dantrolene include weakness that may require mechanical ventilation. Other treatments of malignant hyperthermia include stopping use of the volatile anesthetics, hyperventilating the patient and administering 100% oxygen, administering bicarbonate for severe acidosis, controlling fevers, and maintaining temperature below 39° C without causing hypothermia by using iced fluids, surface cooling, and cooling of body cavities if necessary. Monitoring of temperature and vital signs, urinary output, muscle enzymes, glucose, coagulation studies, acid-base status, and gas exchange is recommended.

Two other diseases associated with mutations in RyR1 include central core disease and multiminicore disease, rare congenital myopathies. Central core disease causes infantile hypotonia; muscle biopsy is needed for definitive diagnosis. Multiminicore disease is a nonprogressive congenital myopathy in which infants exhibit hypotonia, ophthalmoplegia, and arthrogryposis. Scoliosis develops in these children and they may eventually require chronic ventilation. Avoidance of triggering agents is advised for these syndromes and for patients with other myopathies. Both malignant hyperthermia and central core disease are thought to be inherited as autosomal dominant diseases, but extensive genetic analysis has revealed overlapping phenotypes.

Monamine Oxidase Inhibitors, Opioid Analgesics, and Serotonin Toxicity

Anesthesiologists routinely ask whether patients are taking monoamine oxidase (MAO) inhibitors because of their many drug interactions, particularly with analgesics. In addition, serotonin toxicity has features similar to malignant hyperthermia and must be distinguished from it. Serotonin toxicity, characterized by the triad of neuromuscular hyperactivity (tremor, clonus, myoclonus, hyperreflexia, and pyramidal rigidity), autonomic hyperactivity (diaphoresis, fever, tachycardia, and tachypnea), and altered mental status (agitation, excitement, and confusion), can be precipitated by the coadministration of MAO inhibitors and serotonin re-uptake inhibitors. Rigidity, increasing arterial carbon dioxide levels, and fever with a temperature higher than 38.5°C are associated with life-threatening toxicity. Ecstasy, or 3,4-methylenedioxymethamphetamine (MDMA), combined with MAO inhibitors, including moclobemide, can lead to fatalities because they act as serotonin releasers. Tramadol, used for pain relief, and venlafaxine, an antidepressant, act as serotonin releasers and have been involved in the development of toxicity with the concurrent administration of MAO inhibitors.

ANAPHYLAXIS IN THE PERIOPERATIVE PERIOD

The incidence of life-threatening hypersensitivity reactions during anesthesia is 1 in 4000 to 25,000. Anaphylaxis is caused by immunoglobulin E (IgE)-mediated reactions (Chapter 261), whereas anaphylactoid reactions produce the same clinical picture but are not mediated by IgE. Anaphylaxis during anesthesia can be manifested as cardiovascular collapse, airway obstruction, and flushing or edema of the skin, singly or in combination, so knowledge of any previous allergic reactions to medications and the nature of the reaction is critical information to communicate to the anesthesiologist and other members of the perioperative team. Neuromuscular blocking agents, such as succinylcholine, and opioid analgesics can cause nonimmunologic release of histamine from mast cells and produce a similar clinical syndrome. Antibiotics, protamine, and blood transfusions, all given routinely during operations (Chapter 180), can also elicit a variety of systemic reactions. About 75% of perioperative hypersensitivity reactions appear to be due to muscle relaxants, especially rocuronium and vecuronium, with a mortality of 3 to 6%. Skin tests, or prick tests to all the substances to which the patient was exposed, and IgE levels are usually performed to determine whether the patient has an allergic reaction and whether it is mediated by IgE.

Latex Allergies

For sensitized patients (Chapter 261), exposure to even low amounts of latex-containing particles is sufficient to induce a severe anaphylactic reaction. A latex-free operating environment, in which no latex gloves or accessories are used, is key in patients with known allergy. Skin prick tests with latex extracts should be considered in patients at high risk for latex allergy. Early aggressive treatment with epinephrine is critical if severe anaphylaxis occurs.

INTRAOPERATIVE MANAGEMENT

Choice of Intraoperative Anesthesia

There are three general classes of anesthesia: general, regional, and monitored anesthesia care. General anesthesia can be achieved with a balanced drug regimen that induces loss of consciousness, which can range from deep sedation requiring only airway support to states requiring full ventilatory support because of weakness and loss of respiratory drive. Both intravenous and inhaled drugs can be used to induce and maintain general anesthesia. In contrast, monitored anesthesia care denotes a state in which patients can still control their airway, do not require ventilatory support, but are sleepy, have less pain, and may be amnestic. The same drugs are often used for general anesthesia and monitored anesthesia care; achievement of the two different conditions requires knowledge of the pharmacokinetics of the drugs (Table 440-1).

Propofol

Propofol, an alkylphenol, is perhaps the most frequently used intravenous anesthetic for induction of anesthesia and is often used for maintenance of

TABLE 440-1 COMMON ANESTHETIC APPROACHES FOR VARIOUS TYPES OF SURGERY

SURGERY ON INTRA-ABDOMINAL OR INTRATHORACIC ORGANS
Examples: cardiac surgery, lung resections, gastric bypass General anesthesia usually administered because mechanical ventilation is often required Drugs include premedication for anxiety with midazolam, general anesthesia with volatile anesthetics (desflurane, sevoflurane, nitrous oxide), neuromuscular blockade, and opioid analgesics* Epidural anesthesia and analgesia also used; examples include ropivacaine, lidocaine, with fentanyl
SURGERY ON LIMBS
Examples: hip replacement, knee replacement, foot or arm surgery Can perform with epidural or spinal anesthesia, depending on the limb. Examples of medications would include tetracaine, lidocaine, ropivacaine, and fentanyl or morphine Can perform axillary or scalene block; examples include lidocaine and ropivacaine For postoperative pain control: can perform regional blocks that leave the catheter in place, including femoral nerve block, axillary nerve blocks
CATARACT SURGERY—LOCAL ANESTHESIA ON EYE WITH OR WITHOUT SEDATION
Examples of drugs used for sedation include midazolam and fentanyl

*Includes the use of opioids given intraoperatively and whose effects extend into the postanesthesia care unit (PACU) or postoperative period, opioids given in the PACU, or opioids given or intended to be given after discharge from the PACU.

anesthesia during short procedures or to achieve deep sedation during monitored anesthesia care. It is lipid soluble and cleared quickly from the central compartment, so it is eliminated rapidly even after long periods of continuous infusion. However, clearance of propofol is changed by gender (men have lower clearance rates than women do), size (children require higher doses), age (elderly patients have decreased clearance rates and experience increased effects with the drug), and narcotics, which decrease its clearance. Because of its predilection for causing apnea, propofol should be administered only by someone with expertise in airway management. Propofol also decreases arterial blood pressure, causes pain with injection, and can precipitate myoclonus. Large quantities of propofol can cause propofol infusion syndrome, which is associated with cardiomyopathy, metabolic acidosis, skeletal myopathy, hyperkalemia, hepatomegaly, and lipemia. Despite these issues, propofol is frequently being used because recovery from propofol is complete within minutes, even after it is given as a prolonged continuous infusion, in contrast to the longer duration of drug effects seen after the administration of other intravenous sedatives.

Propofol is the preferred agent for healthy outpatients undergoing colonoscopy because it leads to earlier discharge and higher patient satisfaction than do other agents.■

When used in higher-risk populations or administered by nonanesthesiologists, however, narcotic/benzodiazepine sedation appears to be safer than propofol for such procedures.■ At a minimum, the use of propofol requires the presence of a provider who can rescue an airway and manage decreased respiration, oxygen saturation, and hypotension.

Midazolam

Midazolam, a benzodiazepine that produces muscle relaxation through a central mechanism, is hypnotic, sedative, anxiolytic, amnesic, and anticonvulsant. Its amnesic and anticonvulsant effects are mediated through α_1 and γ-aminobutyric acid A ($GABA_A$) receptors, and the anxiolytic and muscle relaxation are mediated through α_2 and $GABA_A$ receptors. Only 20% receptor occupancy is needed to produce anxiolysis, whereas unconsciousness requires 60%. Long-term administration of benzodiazepines produces tolerance, which appears to decrease receptor binding and function. Benzodiazepines cause dose-related depression of the respiratory system, with a peak effect achieved at 3 minutes and significant depression persisting for 60 to 120 minutes. The rate of administration of the drug affects the onset of depression: the faster the drug is given, the quicker the respiratory depression occurs. Benzodiazepines and opioids appear to produce additive respiratory depression, including apnea. Unlike propofol, benzodiazepines used alone decrease blood pressure only modestly. Other drugs, particularly those that affect the cytochrome P-450 3A4 enzyme (including azole antifungals, human immunodeficiency virus [HIV] protease inhibitors, and calcium-channel blockers), affect the clearance of midazolam and prolong its half-life *significantly*. There are several reports of prolonged amnesia in HIV-infected patients who received midazolam for conscious sedation. Midazolam also has an active metabolite and is often associated with delirium in the elderly (Chapter 27), perhaps because it impairs both implicit and relational memory.

Opioids

Opioids are classified as naturally occurring (morphine, codeine), semisynthetic (heroin), and synthetic (methadone, fentanyl, remifentanil). They can be administered both intravenously and in the neuraxial space (epidural or spinal). There are four opiate receptors (μ, κ, δ, and nociceptin receptors), which are G protein–coupled receptors. Chronic exposure to agonists leads to cellular adaptation mechanisms that are probably involved in tolerance, dependence, and withdrawal. Clinically, μ-agonists are used almost exclusively; μ-agonists include morphine, fentanyl, and meperidine. Opioid analgesics are administered because they relieve pain, but they have other important adverse effects, including respiratory depression, decreased gastric emptying, nausea and vomiting, sedation, constipation, pruritus, dependence, and tolerance, when given repeatedly. When opioids are given with propofol or benzodiazepines (or with both), there is a synergistic depressive effect on respiration, hence the rationale for monitoring patients who receive medications for conscious sedation.

Ketamine

Ketamine is unique among the intravenous agents because it has analgesic properties and decreases tolerance to opiates. Ketamine produces dose-related analgesia, which may be profound even when patients can keep their eyes open, breathe spontaneously, and protect their own airway with conserved swallowing and cough reflex. Side effects include increased lacrimation, salivation, and muscle tone. Ketamine increases cerebral blood flow, can increase seizure activity, and can produce undesirable psychological reactions; these side effects are dose related and may be minimized by the concomitant use of benzodiazepines. Ketamine is also a bronchial smooth muscle relaxant and can prevent experimentally induced bronchospasm. Ketamine is usually associated with an increase in blood pressure, heart rate, and cardiac output. These features make ketamine a useful drug for sedating patients with hemodynamic instability.

Dexmedetomidine

Dexmedetomidine is a highly selective α_2-agonist that is associated with less respiratory depression and more cooperative behavior than propofol is. Dexmedetomidine also causes hypnosis, analgesia, sympatholysis, and inhibition of insulin secretion. It induces sedation that has a respiratory pattern and electroencephalographic changes similar to those of natural sleep. Even high concentrations of dexmedetomidine are associated with preservation of spontaneous respiration; however, when dexmedetomidine is administered in combination with sympatholytic or cholinergic agents, there is a high risk for extreme bradycardia and sinus arrest. Dexmedetomidine is associated with less amnesia than the benzodiazepines are. Although propofol and benzodiazepines have commonly been used in critically ill patients to achieve sedation for procedures or for maintenance of mechanical ventilation, dexmedetomidine appears to have significant advantages over benzodiazepines because it appears to cause less delirium and appears to decrease the time that critical care patients spend on ventilators.■

Volatile Anesthetics

Volatile (inhalational) anesthetics include desflurane, sevoflurane, isoflurane, halothane, and nitrous oxide. Inhaled anesthetics are absorbed through the respiratory epithelium and mucous membranes of the respiratory tract, and they are excreted mainly by exhalation. Access to the circulation is almost instantaneous because of the large pulmonary surface area. The pharmacologic effects of inhaled anesthetics depend primarily on alveolar ventilation, the ventilation-perfusion ratio, coadministered gases, gas flow, and the physicochemical properties of the anesthetic gas rather than on the quantity of drug administered, the extent and rate of absorption, protein binding, excretion, secretion, or metabolism. Based on the available evidence, no inhalational agent appears to be superior to any other.

All inhalational agents, with the exception of nitrous oxide, cause dose-dependent cardiovascular depression. Severe hepatotoxicity, which resulted

in discontinuation of the use of chloroform, carbon tetrachloride, and trichloroethylene anesthetics, leads to fatal hepatic necrosis in 1 in 10,000 patients anesthetized with halothane. This problem appears to occur much less frequently after isoflurane and desflurane exposure. Mild halothane hepatoxicity is self-limited and can occur with a single exposure, whereas fulminant halothane hepatitis occurs only after multiple exposures to the drug, has a high mortality rate (50%), and is associated with antibodies to halothane-altered antigens.

Nitrous oxide, which is the only nonhalogenated agent still being used, is not metabolized in human tissues. It irreversibly oxidizes the cobalt atom of vitamin B_{12}, thereby inhibiting the activity of the cobalamin-dependent enzyme methionine synthase. Individuals with vitamin B_{12} deficiency or with mutations in methionine synthase may be at risk for neurologic injury from nitrous oxide, which should not be used in patients at risk. Exposure to concentrations higher than 10■ ppm may be associated with an increased incidence of abortions and decreased fertility, so exposure should be avoided in patients and personnel at risk. General anesthesia can be achieved only by giving combinations of drugs along with nitrous oxide to achieve the desired effects. Based on the available evidence, one anesthetic does not appear to be superior to any other.

Neuromuscular Blockers

Neuromuscular blockers are used to paralyze muscles to facilitate endotracheal intubation and mechanical ventilation, to decrease shivering during induced hypothermia, or to improve conditions for optimal surgery. Succinylcholine causes prolonged depolarization of the neuromuscular junction, which results in failure to generate an action potential. Within 9 to 13 minutes after the administration of 1 mg/kg of succinylcholine, 90% of muscle strength is restored. The very rapid onset and rapid return of muscle function make succinylcholine a most useful drug for difficult intubations. Side effects of succinylcholine include hyperkalemia, myalgia, masseter spasm, sinus bradycardia and nodal rhythms, and increased intraocular pressure.

Most of the other neuromuscular drugs used by anesthesiologists are nondepolarizing in that they compete with acetylcholine for the neuromuscular junction and can be reversed by increasing the quantity of acetylcholine. Categorization of these drugs is according to their chemical makeup; there are steroidal compounds, benzylisoquinolinium compounds, and other chemical compounds. Clinically, a drug is often chosen for its duration of action, with intermediate agents being used most frequently. These drugs act for 20 to 50 minutes and include vecuronium, rocuronium, atracurium, and cisatracurium. They have different routes of metabolism, so the choice of agent depends in part on the presence of coexisting disease.

Chronic administration of neuromuscular blocking agents is associated with prolonged paralysis, particularly in patients taking steroids concomitantly. Other notable interactions with nondepolarizing agents include the following: antibiotics can increase neuromuscular blockade; magnesium sulfate potentiates neuromuscular blockade; lithium can potentiate neuromuscular blockade with succinylcholine and with pipecuronium; antiepileptic drugs cause resistance to nondepolarizing muscle blockade, so larger doses have to be administered for paralysis; and patients receiving anticonvulsants have accelerated recovery from neuromuscular blockade.

Regional Anesthesia

Regional anesthesia involves the deposition of local anesthetics near nerves, including deposition in the epidural space and into cerebrospinal fluid (CSF). Local anesthetics, which are aminoesters or aminoamides, affect cardiac function, as well as central nervous system function when administered systemically.

Binding of the local anesthetic to sodium channels in the axoplasm prevents opening of the channels and conduction of nerve impulses. The rates of onset and recovery from nerve blockade are controlled by diffusion of the local anesthetic into and out of the whole nerve.

Examples of regional anesthesia include neuraxial techniques, deposition of local anesthetics near the brachial plexus to anesthetize the arms (axillary or interscalene blocks), deposition near the femoral or sciatic nerves to anesthetize the legs, deposition near the ulnar or radial nerves for lower arm blocks, deposition near the pudendal nerves for groin procedures, and deposition of local anesthetics into the caudal space for groin surgery. Dentists use this technique frequently when they inject local anesthetics near various nerves in the oral cavity. Many surgeries, including carotid surgery and placement of fistulas for dialysis, can be performed with regional anesthesia. Regional anesthetics may also require supplementation with sedation or general anesthesia.

The dangers associated with regional anesthesia include injection of local anesthetic into the systemic circulation. Systemic toxicity is manifested as convulsions and respiratory depression, which can require assisted ventilation. Tinnitus, visual and auditory disturbances, and dizziness are signs of milder central nervous toxicity. Cardiac toxicity can be manifested by decreases in heart rate, prolonged conduction times, and negative inotropic effects. Bupivacaine toxicity is associated with ventricular fibrillation. Twenty percent Intralipid at various doses (1 mL/kg for three doses and then infusion at 0.25 mL/kg/min or 1.2 mL/kg as a single dose followed by infusion at 0.5 mL/kg/min) has been reported in case reports and animal studies to reverse these toxic effects, although optimal dosing has yet to be determined. Furthermore, the prolonged duration of many of the local anesthetics may require the institution of cardiopulmonary bypass until the drugs are metabolized.

Neuraxial (Spinal and Epidural) Anesthesia and Analgesia

Spinal anesthesia is achieved by instilling local anesthetics into the CSF. Epidural anesthesia is the instillation of larger volumes of local anesthetics into the epidural space, or the potential space between the dura mater and the walls of the vertebral canal. Spinal anesthesia is associated with an increased incidence of headache in younger patients, so epidural anesthesia is often used in younger patients. Complications of epidural and spinal anesthesia and analgesia include failed blocks, post–dural puncture headaches, and toxicity from the local anesthetics. Another major concern with neuraxial anesthesia is that epidural hematoma may develop in patients taking antiplatelet agents, although it remains a rare event that occurs in fewer than 1 in 150,000 operations, even in the presence of potent antiplatelet agents. Other rarer complications of epidural and spinal anesthesia, in addition to the effects of local anesthesia outlined earlier, include intracranial subdural hematoma, transverse myelitis, hypotension, and cardiac arrest.

Postoperative epidural analgesia, in which either local anesthetics or local anesthetics and narcotics are instilled into the epidural space for postoperative pain control, is associated with superior pain control, lower doses of opioids, improved bowel mobility, slightly decreased length of stay in the intensive cause unit, and a slight decrease in the requirement for mechanical ventilation.[4,5]

GENERAL VERSUS REGIONAL ANESTHESIA

The decision regarding which type of anesthesia to administer often depends on the requirements of the surgery. For example, laparoscopic surgery requires general anesthesia because insufflation of gases impairs the ability to breathe adequately. General anesthesia is also required for surgeries on the airway or thorax because mechanical ventilation is needed to sustain adequate respiration. Procedures that do not allow any movement (e.g., precise procedures in the brain) often require general anesthesia and paralysis.

Side effects of general anesthesia depend on the drugs used to achieve anesthesia, whether neuromuscular blockade is administered, and whether mechanical ventilation is needed. Complications of endotracheal intubation include local pain, airway trauma, swelling, vocal cord paralysis, increased bronchospasm, and death from improper placement. Volatile anesthetics are associated with postoperative atelectasis (Chapter 90), whereas regional anesthesia helps preserve respiratory dynamics. Postoperative cognitive dysfunction (Chapter 27) does not seem to depend on the type of anesthesia used.

NAUSEA AND VOMITING

Postoperative nausea and vomiting are more likely with volatile anesthetics but are also common when perioperative opioids are administered. Prophylactic ondansetron, dexamethasone, and droperidol each reduce postoperative nausea and vomiting independently by about 26%, with the main predictor for efficacy being the patient's risk for nausea and vomiting.[6] It should be noted that droperidol has received a "black box" warning from the Food and Drug Administration, so is not used very often in the United States. Total intravenous anesthesia with propofol reduces postoperative nausea and vomiting by only about a fifth, often because narcotics are still administered. The use of spinal or epidural anesthesia (or both) may decrease the incidence of nausea and vomiting. In addition to general anesthesia, risk factors for postoperative nausea and vomiting include female gender, a previous history of nausea and vomiting, a history of motion sickness, nonsmoking, and

intended administration of opioids for postoperative analgesia. If three or more risk factors are present, it is generally recommended that patients receive at least two prophylactic pharmacologic antiemetic agents of different classes (e.g., selected among ondansetron or another 5-HT_3 antagonist, droperidol, dexamethasone, scopolamine, or phenothiazides) preoperatively for the prevention of nausea and vomiting.

POSTOPERATIVE CARE AND COMPLICATIONS

DONALD A. REDELMEIER

POSTOPERATIVE CARE

Overview

Postoperative medical complications are common, sometimes serious, and vary substantially across different settings. Large national studies, for example, show about a two-fold difference in risk for mortality between high- and low-ranked hospitals. However, analyses disagree about how much these differences reflect a greater incidence of each complication (failure of prevention around the time of surgery) or a heightened lethality of each complication (failure to rescue in the aftermath of the operation). Regardless of the explanation, the purpose of medical consultation is to relieve human suffering by the prevention, detection, and correction of postoperative complications. The main constraint is that the consultant often has little ongoing direct contact with the patient before or after the perioperative interval.

Team Psychology

The medical consultant in the postoperative setting must have both knowledge of medicine and an appreciation of team psychology (Chapter 438). In contrast to other settings, the internist is not the team leader, often does not maintain an ongoing relationship with the patient, and does not have the authority of the most responsible physician. Moreover, patients may be dispersed across diverse surgical services, each with their own orientation and culture. The challenges of coordination and communication are enormous, particularly given the multiple other health care professionals involved in complex surgical cases. Considerable tact is often needed to avoid antagonizing the surgeon, disrupting the team's dynamics, or inducing a cascade of cumbersome inopportune testing.

Focusing on Recovery

Facilitating the patient's recovery from surgery differs somewhat from managing patients with acute exacerbations of chronic disease. In the postoperative setting, many therapies need to be discontinued at some point because the patient has recovered, such as discontinuing a urinary catheter because the patient can now void spontaneously or discontinuing a major tranquilizer because the patient is now orientated and coherent. Discontinuation of many other interventions requires substantial judgment, such as the decision when to discontinue intravenous access, supplemental oxygen, and intermittent laxatives. Much depends on experience and reconsideration of an individual patient's situation on a regular basis.

Reading Anesthesia Records

A focused review of the anesthesia record is essential because the consultant is rarely present during the operation. Perhaps the most basic information to identify is the date of surgery because the time elapsed helps in interpreting the patient's current state of recovery. Moreover, sometimes the date is not immediately evident if more than one surgery has been performed, a planned operation was canceled, or misquotations arise. Data about the duration of surgery, type of anesthesia (e.g., regional, spinal, or general [Chapter 440]), and major intraoperative events help establish reasonable expectations about the future course, as well as the possibility of specific complications (e.g., epidural hematoma after spinal anesthesia). Sharing some of the basic data with the patient is often helpful because a surprising number either benefit from repetition or are not otherwise informed.

Patterns of Mistakes

Medical errors (Chapter 11) that arise in postoperative care often seem mundane in retrospect yet can be lethal if undetected. Some patterns of mistakes have the feature of "double trouble," such as when a patient has both a potassium level of 2.0 mEq/L and an international normalized ratio of 2.0 but care focuses on only one of these abnormalities. Other mistakes occur because a single problem arises at an awkward moment, such as a patient in whom acute dyspnea develops when another patient is having a seizure. Still other mistakes relate to the fallibility of human memory and attention, such as when a normal blood sugar value in the morning leads clinicians to assume that the level is still normal at night. These errors can result in substantial harm, failure of clinicians to learn from past mistakes, and unprofessional reactions related to embarrassment. None of these patterns are unique to postoperative care, yet the fast and unfamiliar terrain of surgical settings can make even simple mistakes difficult to avoid.

Checking Orders

The first method for reducing errors after surgery is to check the postoperative orders already written for the patient. Such double checking is a tedious task, and clinicians often direct insufficient attention to this review in the mistaken belief that most of the work is already done. Ironically, checking orders written by another clinician sometimes requires more than customary attention because of the challenges of following someone else's legibility, sequencing, and preferences. The set of orders may need to be read twice: once for errors of commission (e.g., a calcium-channel blocker ordered at the wrong dose) and once for errors of omission (e.g., a β-blocker inadvertently not reordered after surgery). A classic mistake on postoperative orders is failure to follow through on interventions initiated immediately before surgery (e.g., endocarditis prophylaxis). A particularly vexing issue is the need for repeated rechecking on subsequent days (e.g., new orders for sedative drugs).

Recommended Prophylaxis

Some complications are sufficiently frequent and serious that routine prophylaxis is merited in the postoperative setting. For example, antibiotics are indicated for patients at high risk for endocarditis (Chapter 76). Systemic anticoagulation with heparin is indicated for patients at high risk for postoperative deep vein thrombosis (Chapters 37 and 81). Gastric acid suppression

(Chapter 141) is justified for patients at high risk for postoperative gastric bleeding. Parenteral antibiotics are indicated for patients undergoing prosthetic joint replacement. The optimal method for gauging whether a patient is at high risk for each complication is contentious and thereby leads to variation in practice patterns across different settings.

Future Prevention

A postoperative consultant who maintains communication, facilitates the patient's recovery, and avoids postoperative mistakes also has the chance to initiate unrelated medical interventions for general medical care. Such opportunities for prevention might include influenza vaccination, colon cancer screening, or cholesterol reduction. The main advantage of such comprehensive care is that it conforms to the ideal of providing all services possible to the individual. The main disadvantage of such comprehensive care is the potential for creating unintended chaos, confusion, or misquotation (Chapter 438). Such unintended consequences distract the surgical team from the primary goal and also carry some risk for complications from the comprehensive care at a time when the patient is trying to recover from surgery. Many effective postoperative consultants will defer such opportunities for prevention to the physicians who assume long-term responsibility for the patient's care.

COMPLICATIONS

Symptoms

Chest Pain

Chest pain is a common problem after surgery and has an extensive differential diagnosis (Chapter 50). In the postoperative setting, the immediate consideration is an acute ischemic myocardial event. The diagnosis of postoperative myocardial infarction (MI) differs somewhat from community-acquired MI (Table 441-1). Interpretation of a patient's symptoms, examination, and electrocardiogram is often problematic because of changes related to surgery and anesthesia. Instead, diagnosis is heavily dependent on biomarkers such as an elevated troponin level, especially since many postoperative MIs are painless. Management priorities include supplemental oxygen, heart rate control, and correction of hemoglobin. Thrombolysis is often contraindicated, but percutaneous coronary intervention may be considered. In the absence of data from randomized trials, other therapies such as aspirin, statins, and angiotensin-converting enzyme inhibitors should be used on a case-by-case basis (Chapter 73).

Dyspnea

Shortness of breath (Chapter 83) after surgery has an extensive differential diagnosis (Table 441-2). The three key considerations are fluid overload/heart failure (Chapter 58), pulmonary embolism (Chapter 98), and air space disease (a continuum encompassing atelectasis [Chapter 90], bronchitis [Chapter 96], aspiration [Chapter 94], mucous plugging, and pneumonia). Distinguishing among these three considerations requires focusing on the speed of onset, the timing relative to surgery, vital signs, findings on oximetry, and the physical examination (Chapter 83). Fluid overload is most commonly seen soon after the cessation of positive-pressure ventilation or vasodilating neuraxial anesthesia or analgesia. It is also common 3 to 5 days postoperatively when fluid that has been "third-spaced" is mobilized into the intravascular compartment. Interventions that are safe in most situations include administration of oxygen and withholding sedation. The use of continuous positive airway pressure can reduce the rate of reintubation in hypoxemic postoperative patients. Other interventions that will be helpful or harmful, depending on the specific situation, include diuretics, elaborate medical imaging, and vigorous physiotherapy.

TABLE 441-1 CRITERIA FOR DIAGNOSING POSTOPERATIVE MYOCARDIAL INFARCTION

The diagnosis of perioperative MI requires any one of the following criteria:
Criterion 1: A typical rise in the troponin level or a typical fall in an elevated troponin level detected at its peak after surgery in a patient without a documented alternative explanation for an elevated troponin level (e.g., pulmonary embolism) or a rapid rise and fall in CK-MB only if troponin measurement is unavailable.* This criterion requires that one of the following criteria be met: Ischemic signs or symptoms (e.g., chest, arm, or jaw discomfort; shortness of breath; pulmonary edema) Development of pathologic Q waves on an ECG Changes on an ECG indicative of ischemia Coronary artery intervention New or presumed new cardiac wall motion abnormality on echocardiography or new or presumed new fixed defect on radionuclide imaging
Criterion 2: Pathologic findings of acute or healing MI
Criterion 3: Development of new pathologic Q waves on an ECG if troponin levels were not obtained or were obtained at times that could have missed the clinical event

*Because CK-MB is both less sensitive and less specific than troponin levels in the perioperative setting than in other settings, it should be used for diagnostic purposes only when troponin levels are not obtainable.

CK-MB = creatine kinase MB isoenzyme; ECG = electrocardiogram; MI = myocardial infarction.

Reproduced with permission from Devereaux PJ, Goldman L, Yusuf S, et al. Surveillance and prevention of major perioperative ischemic cardiac events in patients undergoing noncardiac surgery: a review. *CMAJ*. 2005;173:779-788.

Anorexia

Loss of appetite after surgery has an extensive differential diagnosis (Chapter 134) that can be narrowed substantially if the patient was eating properly before surgery. The immediate priority is to search for and correct underlying contributors. Oral, enteral, or parenteral support is not the priority initially, although such support may become necessary. Drug toxicity is a particularly common, easily detected when considered, and rapidly reversible contributor to postoperative anorexia. Anatomic abnormalities are usually evident by medical imaging studies. Other common metabolic contributors include abnormalities in electrolytes, calcium, phosphorus, and magnesium. Acalculous cholecystitis (Chapter 158) is an important postoperative complication that must be considered in a patient with right upper quadrant tenderness. Multiple antinausea medications are available for symptomatic relief (e.g., ondansetron, dexamethasone, droperidol) and act in an additive manner when used in combination.

Vomiting

Vomiting is the extreme form of nausea in the postoperative setting, and the two symptoms share the same differential diagnosis. In most patients, vomiting is rare and unexpected and merits immediate care. Initial management is to ensure that the patient's airway is protected, discontinue oral medications (and find parenteral substitutes if necessary), and consider insertion of a nasogastric tube. In patients after gastrointestinal surgery, the priorities are to consider the possibility of an anastomotic leak, peritoneal abscess, or other anatomic abnormality. In patients after operations on more remote parts of the body, the priorities are emetogenic medications (such as postoperative chemotherapy), gastroparesis associated with autonomic neuropathy, and fecal impaction. If no reversible contributor is identified, the default diagnosis is prolonged idiopathic ileus, and a therapeutic trial of intravenous neostigmine can be considered.

Diarrhea

Diarrhea (Chapter 142) is relatively rare after surgery and involves a limited number of possibilities if the patient's bowel movements were normal before surgery. In such cases the situation represents an acute-onset diarrhea that is usually secretory in nature. The immediate priority is to exclude toxic megacolon, which is caused by overgrowth of toxigenic *Clostridium difficile* and is a potential emergency. Clinical evaluation for toxic megacolon requires assessment for tachycardia, hypotension, delirium, and other signs of sepsis rather than waiting on initial stool studies for confirmation of infection with *C. difficile*. Risk factors for antibiotic-associated diarrhea include advanced age, use of broad-spectrum antibiotics (e.g., third-generation cephalosporins), and unknown host susceptibility factors (e.g., past episodes of pseudomembranous colitis). Frequently, a definitive diagnosis is never established and treatment focuses on feeding the patient a lactose-free diet while avoiding intestinal paralytics. Complete resolution is typical, provided that adequate fluid and electrolyte levels are maintained.

Weakness

Generalized weakness after surgery is almost inevitable, but focal weakness may reflect nerve damage caused by intraoperative positioning (e.g., damage to the facial nerve after carotid endarterectomy) and rarely indicates a spontaneous new intracranial event (e.g., intracerebral bleeding [Chapter 415] secondary to anticoagulation). Such deficits are often overlooked during the initial postoperative interval and may become apparent only after the patient has regained strength elsewhere in the body. Conversely, new deficits that are

TABLE 441-2 DISTINGUISHING AMONG COMMON CAUSES OF ACUTE POSTOPERATIVE DYSPNEA

	PULMONARY AIR SPACE	FLUID OVERLOAD/HEART FAILURE	PULMONARY THROMBOEMBOLISM

evident early after surgery and resolve rapidly thereafter may reflect an old stroke that is fully compensated during less stressful circumstances. Medical imaging of the brain is worthwhile if no explanation is apparent on initial assessment. Nonfocal weakness commonly responds to physical therapy.

Delirium

Changes in mental status after surgery are common, especially in elderly patients (Chapter 27), and can be remarkably difficult to diagnose and correct. The immediate priority is to determine whether the impairment is acute or chronic and to detect easily reversible contributors (such as infection, hypoglycemia, alkalosis). A complete assessment is often unnecessary if the patient had normal mental status before surgery because many dementia syndromes are thereby excluded (such as vitamin B_{12} deficiency, tertiary syphilis, Alzheimer's disease). Immediate treatment usually focuses on discontinuing medications, especially anticholinergics, narcotics, and tranquilizers. The patient may also benefit from the continuous presence of friends and family members, who can provide frequent orientation and constant attention. A sense of patience is necessary because delirium rarely resolves instantly. The benefit of low-dose neuroleptics (e.g., risperidone, 0.5 mg twice daily) remains uncertain.

Seizures

The development of uncontrolled seizures (Chapter 410) after surgery is rare. The immediate priority is to exclude status epilepticus, uncover any past history of a chronic seizure disorder, and identify provocative factors. Neurosurgical patients typically undergo a standardized treatment protocol, including steroids and imaging. Other conditions that can cause abnormal movement, such as septic rigors, delirium tremens, Parkinson's disease, major psychopathology, hypothermic shivering, and hypercapnic asterixis, must be excluded. Additional considerations include detecting and correcting any underlying metabolic abnormalities such as hypocalcemia, hypoxemia, hyponatremia, hypophosphatemia, and drug toxicity. Treatment focuses primarily on reversing the underlying precipitating cause and providing nonspecific care with benzodiazepines, phenytoin, and ongoing monitoring.

Signs

Hypertension

Hypertension may reflect a variety of disorders and must be treated in a manner that neither overreacts nor underreacts to the situation. Hypertension is particularly common after neurosurgical procedures or carotid endarterectomy. The initial assessment focuses on whether the patient has chronic hypertension based on the past history, current electrocardiogram, or findings on funduscopy. Special attention should also be directed toward excluding undertreated pain, agitated delirium, fluid overload, alcohol withdrawal, and inadvertent discontinuation of chronic antihypertensive medications. In uncertain cases, systemic analgesia is often helpful, along with nitrates (e.g., nitroglycerin, 0.4 mg/hr transdermally) and β-blockers (e.g., metoprolol, 5 mg intravenously). The major complication of treatment is the potential for overcorrection and inadvertent hypotension—such errors are particularly common in patients with no evidence of past hypertension.

Hypotension

Hypotension (Chapter 7) after surgery is generally an emergency, and the immediate concern is often internal bleeding, especially after intra-abdominal operations or when anticoagulation is used to prevent venous thrombosis. The initial stages of hypotension are frequently unrecognized because of biologic stress responses by patients, psychological denial by clinicians, and misattribution to the concurrent use of analgesia. Early hypotension is particularly easy to miss if the patient has coexisting chronic hypertension and the apparently "normal" blood pressure is dismissed as unremarkable. Treatment usually entails volume supplementation, serial assessment, vasopressors as needed (Chapters 107 and 108), and a search for underlying causes, especially possible sepsis. Sometimes an extensive differential diagnosis needs to be considered if no anatomic cause related to surgery is evident (Chapter 106). Routine use of pulmonary artery catheters for diagnosis or to guide therapy is not helpful.■

Tachycardia

Tachycardia after surgery can be caused by a myriad of arrhythmias (Chapters 64 and 65) and may contribute to postoperative cardiac ischemia.

Distinguishing between newly identified and newly incident tachycardia can sometimes be accomplished by determining whether the patient does or does not complain of palpitations. The initial assessment almost always requires review of the electrocardiogram to distinguish atrial fibrillation from other disorders. The goal of treatment is to identify and correct precipitating factors such as pain, blood loss, hypoxia, electrolyte abnormalities, fluid overload, hypotension, pulmonary embolism, and drug withdrawal. Most arrhythmias respond to correction of the underlying abnormality. Specific antiarrhythmic treatment, when needed, is generally similar to that used in the nonoperative setting (Chapters 64 and 65). For atrial fibrillation, anticoagulation is sometimes contraindicated; in such situations, cardioversion within 48 hours merits consideration.

Fever

Fever (Chapter 288) after surgery is common, frequently perplexing, and often multifactorial. Worrisome possibilities include transfusion reactions (Chapter 180), hospital-acquired pneumonia (Chapter 97), urinary tract infection (Chapter 292), line sepsis (Chapter 290), and wound infection. In many cases no definitive cause is found, the patient recovers spontaneously, and the default diagnosis is atelectasis. Detailed evaluation, when necessary, requires culture of blood, urine, and the wound to identify specific microbiologic organisms. Selection of empirical antibiotics is usually based on local practice patterns and hospital ecology, with the main disadvantage being the breeding of resistant organisms. Hydration, nutrition, and general supportive care are important, yet frequently neglected needs of patients with prolonged elevations in body temperature.

Edema

Peripheral edema (Chapter 50), which is often first noticed by nursing staff after surgery, is rarely life-threatening unless treated with excessive diuretics. The cause is frequently multifactorial and includes both increased hydrostatic pressure (including heart failure and gravity from intraoperative positioning), decreased oncotic pressure (related to hypoalbuminemia from decreased liver production or increased losses), and capillary leak (potentially caused by medications or tissue reactions). Treatment focuses on correction of any underlying abnormalities, maintenance of nutrition, judicious use of diuretics, monitoring of renal function, provision of systemic anticoagulation against deep vein thrombosis, and efforts toward mobilization of the patient. Selected use of echocardiography, a low-salt diet, afterload reduction, and spironolactone may be helpful in patients in whom heart failure (Chapter 59) is the dominant mechanism.

Laboratory

Leukocytosis

An elevated white blood cell count (Chapter 170) can have many causes, but the immediate priority is to exclude a life-threatening septic process (Chapters 106 and 108). Direct microscopic examination of the peripheral blood smear (Chapter 160) can be helpful to check for toxic granulations (see Fig. 160-18), Döhle's bodies (Fig. 160-19), and a shift toward primitive band cells. Many cases are caused by noninfectious causes, including infarcted tissue (brain, heart, intestinal tract), inflammatory conditions (renal insufficiency, diabetic ketoacidosis, lupus erythematosus), or demargination stress reactions (dehydration, systemic corticosteroids, inotropic medications). In the absence of direct evidence, some clinicians may initiate antibiotics empirically, whereas others may elect waiting. Substantial controversy remains about the proper duration of an empirical trial of antibiotics when no cause is discovered and the patient is otherwise recovering.

Anemia

Anemia (Chapter 161) is common and sometimes underappreciated because coexisting volume depletion causes the blood hemoglobin concentration to underestimate the degree of blood loss. The initial priority is to differentiate bleeding at the surgical site from other causes. In many cases the exact cause is unclear and substantial uncertainty may arise over the need to initiate gastric acid suppression therapy or sacrifice systemic anticoagulation originally directed against venous thrombosis. Guidelines for transfusion therapy depend on the patient's cardiac reserve, as well as the available blood bank supply at the particular medical center. A reasonable goal is to maintain a hemoglobin level of 7 mg/dL or higher, except in patients with cardiovascular disease, in whom a hemoglobin goal of 10 mg/dL is reasonable. The immediate postoperative interval is not usually the appropriate time to initiate erythropoietin, oral iron replacement, or detailed evaluations for other hematologic abnormalities.

Abnormalities in Platelet Count

Patients often have abnormal platelet counts after surgery yet rarely require further evaluation or treatment. In most cases the thrombocytopenia is mild, does not require transfusion therapy, resolves in a few weeks, and is not a sign of an ominous disorder (e.g., sepsis or heparin-induced thrombocytopenia). Platelet transfusions are indicated if the decrease in platelet count is extreme, accompanied by evidence of major blood loss, or related to recent surgery on the central nervous system (including the eye). Thrombocytosis is also common about a month after surgery and is occasionally extreme. However, even postoperative thrombocytosis exceeding 1,000,000/mL rarely necessitates treatment, does not predispose patients to unwanted clotting disorders, and typically resolves spontaneously after a few weeks.

Abnormal Sodium

Both hyponatremia and hypernatremia (Chapter 118) are frequent complications in the postoperative setting. The immediate priority is to assess the patient's intravascular volume status and correct possible volume depletion. The cause of hyponatremia is often multifactorial, including excessive use of diuretics, excess intrinsic antidiuretic hormone (as a result of factors such as drugs, pain, or mechanical ventilation), and unmeasured osmoles (e.g., intravenous contrast agents). This risk for postoperative hyponatremia may be more effectively reduced by the administration of isotonic saline rather than by water restriction. Once hyponatremia develops, vasopressin antagonists (Chapter 118) are effective for both hypervolemic and euvolemic hyponatremia. Hypernatremia is always due to free water deficiency, which may indicate severe cognitive impairment or other factors interfering with the ability to express thirst or ingest water. Correction is similar to that in the nonoperative setting. Abnormalities in sodium concentration require careful follow-up, can develop or recur at any point after an operation, yet are rarely the root cause of a patient's inability to recover from surgery.

Abnormal Serum Potassium

Hyperkalemia and hypokalemia (Chapter 119) are also frequent postoperative complications. The immediate priority is to assess and stabilize the patient's electrocardiographic findings. Hyperkalemia is usually due to cellular shifts, renal failure, and tissue destruction (including hemolysis). Hyperkalemia will generally correct with treatments that shift potassium into cells (e.g., intravenous glucose with or without insulin or β-agonists) and enhance excretion (e.g., gastrointestinal binding agents). Hypokalemia is usually due to inadequate intake, excessive loss, or cellular shifts. Hypokalemia will generally correct with replacement therapy and rarely requires aldosterone antagonism. Both abnormalities can usually be treated as in the nonoperative setting (Chapter 119). The prognosis is favorable if the patient's electrocardiogram shows no major abnormalities and renal function is preserved.

Alkalosis

Systemic alkalosis (Chapter 120) typically requires volume supplementation because the cause is generally intravascular volume depletion. Blood gas determinations may be necessary in some cases to exclude the possibility of concurrent carbon dioxide retention with compensatory metabolic alkalosis. Untreated, alkalosis can result in altered mentation, cardiac arrhythmias, and delayed mobilization. Most patients with postoperative alkalosis do not require carbonic anhydrase inhibitors or intravenous acid. The prognosis is usually favorable, with gradual correction over a period of several days. Rapid correction of alkalosis, unlike rapid correction of hyponatremia, is not known to cause neurologic injury.

Azotemia

The initial assessment of an elevated serum creatinine concentration (Chapter 116) focuses on reviewing previous values (to distinguish acute from chronic renal insufficiency) and identifying contributing factors (such as prerenal volume depletion, intrarenal nephrotoxins, or postrenal urethral obstruction). A trial of intravenous fluids may be useful on both a diagnostic and therapeutic basis. Treatment is the same as in the nonoperative setting. Subsequent monitoring is always necessary, with serum creatinine measurements obtained on a daily basis. Serial measurements of urinary volume and body weight and urine cultures are occasionally helpful in selected cases. The

prognosis is dependent on the underlying factors and is less favorable after cardiac surgery.

Hyperbilirubinemia

Elevations in serum bilirubin (Chapter 149) are rare after surgery, even though abnormalities in liver enzyme levels occur frequently with general anesthesia. The most benign explanation is Gilbert's syndrome, but the immediate priority is to assess for possible hepatic failure (especially in patients who have received halothane). As in the nonoperative setting, treatment involves withdrawing potential hepatotoxins, supporting the patient, and allowing time for liver function to recover (Chapter 157). Treatment of hepatic encephalopathy is particularly important because of the constipation and generalized catabolic state that follow major surgery. Monitoring should include serial measurement of liver function on a daily basis because each component (e.g., bilirubin, albumen, prothrombin time) can be altered in postoperative patients by factors unrelated to the liver. The prognosis is unfavorable if the patient's liver function fails to recover quickly.

Hypoalbuminemia

Reductions in serum albumin are common after surgery and are an ominous prognostic finding. The cause is rarely decreased production if the loss of albumin occurs rapidly. Possible explanations include nephrotic syndrome, capillary leak into extravascular spaces, and occult catabolism in unrecognized sites. Treatment with albumin infusions does not usually normalize the biochemical abnormality and does not seem to improve patient mortality rates significantly. The main priorities are to continue nutritional support, preserve skin integrity, minimize the use of systemic diuretics, correct any contributing factors, and consider correlated serum protein deficiencies (such as reduced levels of immunoglobulins or antithrombin III). Hypoalbuminemia can also cause indirect harm by the loss of carrier proteins, which predisposes patients to unwanted episodes of drug toxicity. The long-term prognosis is favorable for survivors because the serum albumin level will eventually fully return to normal.

Blood Glucose Abnormalities

In patients with diabetes mellitus (Chapter 236), serum blood sugar concentrations often become erratic after surgery because of altered dietary intake, decreased physical activity, and release of counter-regulatory hormones. The priorities are to avoid hypoglycemia, severe hyperglycemia, diabetic ketoacidosis, cerebral damage, and repeated events. Intensive control of the blood glucose level increases the risk for severe hypoglycemia and death, so a target glucose level of about 140 to 200 mg/dL is recommended.■ Rapid reversal of sepsis or focal infection can lead to a precipitous decrease in insulin requirements; in such cases, vigilance is required because unsuspected hypoglycemia may cause permanent damage or be fatal in a patient who may seem to be sleeping. Patients need to be forewarned that temporary doses of subcutaneous insulin may be required but do not commit the patient to chronic insulin therapy. Monitoring involves serial measurement of blood sugar until the patient is eating in a reliable manner.

Special Situations

Multiplicity

Some postoperative complications are difficult to classify because no single dominant problem is apparent by symptoms, signs, or laboratory testing. Instead, the patient has two or more problems that need to be addressed simultaneously. The immediate goal is to set priorities and avoid the temptation to try to eliminate every possibility on the first day. The corollary is to continue to check progress over the many days that may be required for complete diagnosis and successful therapy. Because so many concerns require attention in the postoperative interval, the risk is that clinicians will lose track of a secondary issue and make an error that seems obvious in retrospect.

Redundancy

Postoperative complications sometimes generate multiple consultations with physicians who have overlapping abilities. An example might be a patient with a postoperative fever that prompts consultations from pulmonology, nephrology, dermatology, general medicine, and infectious diseases. In theory, gathering a critical mass of medical experts together should increase the likelihood of accurate diagnosis, timely treatment, and foolproof follow-up. In reality, however, coordination and communication are never perfect. Personal rivalries, diffusion of responsibility, and many other psychological factors may impede interactions among consultants. Opportunities for miscommunication may be further accentuated if the patient has an exotic diagnosis that is a special draw on the consultant's attention (e.g., pheochromocytoma). Arguing in front of the patient, in view of other professionals, or in the medical record can be demoralizing. The priority is to communicate effectively with the surgical team responsible for the patient and encourage that team to make the final decision.

Ambiguity

Another vexation occurs when an urgent request is not connected to a clear rationale (Chapter 438). Diplomacy is needed to establish whether the motivation reflects medicolegal concerns rather than a biologic change in the patient. Sometimes the stimulus that drives the consultation can best be addressed by providing reassurance and confirmation. Sometimes the stimulus is an obscure preexisting disorder (e.g., moyamoya disease), and the surgical team has neither the experience nor the time to investigate how this unrelated medical condition can influence recovery from surgery. Sometimes the stimulus is an unspoken political wish to transfer the care of a burdensome patient from one physician to another. A consultant should develop an understanding of how to interact with other clinicians under such ambiguous circumstances.

Setting Priorities

Requests for consultation often arrive outside conventional working hours, are usually tinged with a sense of urgency, and sometimes cluster to encompass more than one patient. Developing an effective method for prioritizing patients is a crucial clinical skill. One communication strategy is to provide an objective estimated time of arrival for the initial request from the surgical team. An oftentimes helpful treatment strategy is to make some safe suggestions at the time of the initial request so that clear-cut recommendations can be instituted during the interval before the patient is seen and used later to help evaluate the patient's status and course.

Ending

In many postoperative cases, the original reason for consultation may resolve and no major issues remain. The situation now provides an opportunity to review the patient, particularly for the appropriate use of unrelated medications. The consultant may often detect excessive medications that were appropriate early in the hospital course but have ceased to be necessary, thereby justifying discontinuation (e.g., diuretics, antibiotics, bronchodilators). Discontinuing medications that have become superfluous requires initiative and wisdom, and the common mistake is to propagate unnecessary medications in stable patients under the rationale of "don't mess with success." The ability to watch the patient for several hours or for a day or two often presents an ideal opportunity for the safe withdrawal of medications. Ironically, discontinuing a treatment sometimes requires more skill, time, and initiative than starting it.

MEDICAL CONSULTATION IN PSYCHIATRY

PETER MANU

HEALTH STATUS IN PSYCHIATRIC PATIENTS

The physical health of psychiatric patients is poor, with a higher risk for death at an early age than in the mentally sane. The magnitude of the problem is greatest in patients with schizophrenia, who have a significantly shorter lifespan compared with the general population. Poverty, social neglect, substandard medical care, unhealthy life habits, and complications of psychiatric treatments are major contributors to the increased morbidity and mortality of patients with chronic psychiatric disorders, who have a 22.5-year average decline in life expectancy.

MEDICAL EVALUATION IN PSYCHIATRIC SETTINGS

Requirements for medical training in psychiatry vary. In the United States, psychiatric residents have up to 4 months of inpatient medical training. Data suggest that psychiatrists have limited skills in assessing nonpsychiatric problems in terms of history taking, a reluctance to perform physical examinations, and a tendency toward premature diagnostic closure. As a result, medical consultations are often requested for basic medical issues. For example, in one study, 1001 consecutively admitted psychiatric patients generated 2120 initial consultations and 1800 follow-up visits. The highest rate of medical utilization was for patients with dementia, schizophrenia, substance abuse disorders, and mental retardation. Because medical issues may precipitate psychiatric decompensation or be obscured by it, about 10% of psychiatric inpatients seen by a medical consultant required transfer to a medical or surgical unit.

Medical consultation in psychiatry is not more difficult than in other clinical settings but must be informed by knowledge about the serious complications of psychiatric treatments (Table 442-1). This chapter provides details about some of the most important entities specific to the psychiatric setting.

TABLE 442-1 MAJOR MEDICAL COMPLICATIONS OF PSYCHOTROPIC DRUGS

CARDIOVASCULAR	
Cardiomyopathy	Clozapine
Hypertension	MAO inhibitors, venlafaxine
Myocarditis	Clozapine
Orthostatic hypotension	Tricyclics, trazodone, antipsychotics
QTc prolongation	Antipsychotics, tricyclics
Venous thromboembolism	Clozapine, risperidone, phenothiazines
RESPIRATORY	
Choking	Antipsychotics, tricyclics
Laryngospasm	Antipsychotics
Respiratory depression	Benzodiazepines, barbiturates, methadone, antidepressants, atypical antipsychotics
GASTROINTESTINAL	
Bowel obstruction	Tricyclics, antipsychotics
Dysphagia	Tricyclics, antipsychotics
Hepatic impairment	Carbamazepine, valproic acid, phenothiazines, mirtazapine, nefazodone, quetiapine, olanzapine, clozapine, MAO inhibitors, naltrexone
Pancreatitis	Carbamazepine, valproic acid, clozapine, olanzapine
KIDNEY AND URINARY TRACT	
Renal insufficiency	Lithium, clozapine
Urinary retention	Antipsychotics, tricyclics
ENDOCRINE	
Hyperprolactinemia	First-generation antipsychotics, risperidone
Hypothyroidism	Lithium, quetiapine
Inappropriate ADH secretion	Serotonin reuptake inhibitors, methadone, tricyclics
Metabolic syndrome	Clozapine, olanzapine, risperidone, quetiapine
HEMATOLOGIC	
Leukocytosis	Lithium
Neutropenia	Clozapine, olanzapine, risperidone, carbamazepine, valproate, mirtazapine
Thrombocytopenia	Carbamazepine, valproate
MUSCULOSKELETAL	
Rhabdomyolysis*	Antipsychotics, serotonin reuptake inhibitors, MAO inhibitors
SKIN	
Stevens-Johnson syndrome	Lamotrigine, carbamazepine, barbiturates
OTHER	
Fever*	Antipsychotics, serotonin reuptake inhibitors, MAO inhibitors
Seizure	Bupropion, MAO inhibitors, tricyclics, phenothiazines

*Includes neuroleptic malignant syndrome and serotonin syndrome.
ADH = antidiuretic hormone; MAO = monoamine oxidase.

EVALUATION OF CHIEF COMPLAINTS

Medical consultation for psychiatric patients creates unique challenges in evaluation of the chief complaint. Many patients with outpatient psychiatric disorders have somatic symptoms such as fatigue, weakness, dizziness, headache, insomnia, widespread pain, and constipation. In most of these patients, the underlying mental illnesses are mood disorders (unipolar depression and dysthymia), anxiety disorders (panic disorder and generalized anxiety disorder), somatoform disorders, substance use disorders (most often alcohol, opiates, cocaine, and benzodiazepine), and borderline personality disorder. As a group, these patients have many physical complaints and resist a psychological explanation for their symptoms even when the medical evaluation fails to identify objective abnormalities.

In contrast, patients admitted for inpatient psychiatric treatment often have psychotic disorders, developmental abnormalities, or dementia with behavioral disturbance; they are frequently vague or silent about physical suffering and only rarely voice somatic delusions. Such patients may deny pain even after bowel perforation or myocardial infarction.

A rigorous diagnostic evaluation is therefore required to avoid the errors of omission created by the weak correlation between complaints and pathology. This evaluation should include consideration of physical disorders, drug effects (adverse reaction, toxicity, or withdrawal), cognitive impairment (delirium), sensory impairment (loss of vision, hearing, speech, or postural balance), and situational maladjustment (isolation, overload, or loss of privacy). Attribution of symptoms to the patient's psychiatric condition should remain a diagnosis of exclusion.

MEDICAL COMPLICATIONS OF PSYCHIATRIC TREATMENTS

Antipsychotic-Induced Metabolic Syndrome

Metabolic syndrome is more prevalent (range, 29 to 63%) in schizophrenic and other psychiatric patients treated with atypical antipsychotic drugs such as clozapine, olanzapine, risperidone, and quetiapine than in the general population. Clozapine, olanzapine, and quetiapine are the worst offenders because they induce substantial weight gain, thereby leading to insulin resistance (with or without fasting hyperglycemia) and atherogenic dyslipidemia. This gain in weight may be related to affinity for the histamine-1 (H_1) receptor and to neurobiologic mechanisms that regulate appetite and metabolism via the production and activity of serotonin, leptin, and tumor necrosis factor-α. Within 18 months, 30% of patients treated with olanzapine will

increase their body weight by more than 7%, with an average increase of 43 mg/dL in triglycerides, 15 mg/dL in blood glucose, and 0.41% in glycosylated hemoglobin. Not surprisingly, these changes result in about a twofold increased risk for diabetes and coronary heart disease events. Nonetheless, controlled trials have identified olanzapine and clozapine as effective drugs for patients with schizophrenia and other psychotic disorders.

Because the glucose intolerance often seen in patients treated with antipsychotic agents is due to insulin resistance (Chapter 237), it is best treated by aggressive weight reduction, (Chapter 220), increasing physical activity (Chapter 15), and metformin (Chapter 237), or a combination of these. For example, in randomized trials, metformin, 850 mg twice daily, reduced the weight gain associated with the initiation of second-generation antipsychotic drugs,■ and a single daily dose of 750 mg may prevent weight gain if initiated at the onset of olanzapine treatment.■ In treating hypertension, β-adrenergic blockers should be used cautiously in patients receiving neuroleptics because they increase the potential for orthostatic hypotension, syncope, and falls. Smoking cessation programs combining transdermal or transmucosal nicotine replacement, bupropion, and cognitive-behavioral therapy should be strongly recommended despite the dismally high failure rates that have been reported in patients with chronic schizophrenia (Chapter 31).

Antipsychotic-Induced Myocarditis and Cardiomyopathy

Antipsychotic-induced myocarditis and cardiomyopathy (Chapter 60) are most common in patients treated with clozapine (0.9%) and fluphenazine (0.4%). In contrast, the risk for these complications is only 0.1% in patients receiving haloperidol, thioridazine, and risperidone.

The accepted pathophysiologic explanation for myocarditis is an immunoglobulin E (IgE)-mediated acute hypersensitivity reaction, similar to the allergic myocarditis produced by penicillins, sulfonamides, and methyldopa. In a small number of patients, a competing hypothesis proposes that clozapine induces hypereosinophilic myocarditis, colitis, hepatitis, pancreatitis, alveolitis, and interstitial nephritis. A direct cardiotoxic effect of drug metabolites cannot be excluded.

In patients in whom myocarditis develops, the mortality rate is as high as 50%, with almost half the deaths occurring suddenly and unexpectedly. The average duration of exposure to clozapine before diagnosis or death is 21 days, and the dosage range is 50 to 725 mg/day. Common symptoms are fever (48%), dyspnea (35%), flulike illness (30%), chest pain (22%), and fatigue (17%). Laboratory features include left ventricular hypokinesia or reduced ejection fraction (48%) or pericardial effusion (17%) on echocardiography, nonspecific repolarization abnormalities on electrocardiography (35%), peripheral eosinophilia (35%), elevated creatine kinase and troponin levels (22%), and radiographic evidence of heart failure (13%). The diagnosis can be confirmed by endomyocardial biopsy showing fraying of myocytes and perivascular infiltrates with degranulated eosinophils. Among survivors, symptoms resolve or substantially improve after discontinuation of clozapine and treatment with high-dose corticosteroids (e.g., prednisone, 1 mg/kg/day for 4 days, tapered to 0.33 mg/kg/day for the following 4 days).

Clozapine-induced dilated cardiomyopathy may be caused by an evolving myocarditis or by chronic injury mediated by free radicals, similar to the myocarditis produced by doxorubicin (Chapter 60). The demographic features are similar to those of myocarditis, but the mean duration of treatment before diagnosis is much longer (9 months vs. 3 weeks), and the mortality rate is lower (22 vs. 51%). Patients have clinical or echocardiographic evidence of left ventricular dysfunction without eosinophilia or enzymatic evidence of myocardial necrosis.

Prolonged QTc Interval and Sudden Death

Significant prolongation of the QTc interval (Chapter 65) leading to ventricular tachyarrhythmias and sudden cardiac death (Chapter 63) can occur after antipsychotic treatment with the usual doses of thioridazine, haloperidol, and sertindole. Abnormal myocardial repolarization has been observed during treatment with most antipsychotic medications and after intentional or accidental overdoses of tricyclic antidepressants, lithium, and methadone (Chapter 110). All antipsychotics affect the cardiac potassium channel by blocking the rapidly activating component of the rectifier potassium current (Chapter 61). This effect translates into a dose-dependent increase in the duration of phase 3 of the action potential. The drug concentration that produces 50% inhibition of rapid potassium outflow varies for each drug (e.g., 1 nmol/L for haloperidol and 6 nmol/L for olanzapine). Compared with nonusers of antipsychotic drugs, the risk for sudden death is twice as high for current users of conventional (first-generation) antipsychotics and is 2.25 times higher for current users of atypical (second-generation) antipsychotics. All patients about to start antipsychotic drugs should be asked about a personal history of syncope and a family history of long QT syndrome or sudden death at a young age. A baseline electrocardiogram and serum electrolytes should be obtained before starting antipsychotic drug therapy, tricyclic antidepressants, and methadone. Interval electrocardiograms should be obtained after each increase in medication in older patients, patients with known heart disease, and those starting other drugs known to produce QTc prolongation or hypokalemia (Chapter 65). A QTc interval of 500 msec or greater requires the discontinuation of all drugs that affect membrane repolarization. QTc intervals greater than 450 msec in males and 470 msec in females, QTc dispersion (difference between the longest and shortest QTc on a 12-lead electrocardiogram) greater than 100 msec, and an increase in QTc duration of more than 60 msec in comparison to the baseline measurement should prompt reevaluation of the risks and benefits associated with the drugs in question.

Choking and Laryngeal Dystonia

Asphyxia deaths from choking occur at a rate of 0.8% per 1000 psychiatric patients each year, a frequency that is more than 100 times greater than in the general population. In addition, videofluoroscopy demonstrates silent aspiration in 38% of psychiatric patients who survive a choking incident. Choking and silent aspiration are manifestations of dysphagia (Chapter 140), which is common in the mentally ill. Half the psychiatric patients with dysphagia have a fast-eating syndrome seen in association with restlessness, poor chewing skills, food pocketing in the cheeks, and attention deficits that characterize psychotic disorders and mental retardation. Bradykinetic dysphagia, which is seen in 25% of psychiatric patients with choking episodes, is due to the antidopaminergic and anticholinergic effects of psychotropic medications. This condition, which features reduced lingual range of motion, increased oral transit time, decreased pharyngeal peristalsis, and delayed initiation of the swallowing reflex, is seen in patients with neurologic features of drug-induced parkinsonism (Chapter 416). Dyskinetic dysphagia (7% of choking cases), which generally occurs in patients maintained on long-term antipsychotic medication, is part of the clinical spectrum of tardive dyskinesia (Chapter 417). The examination reveals involuntary contractions of the tongue and perioral musculature, clumsiness of voluntary movements of the tongue, and discontinuous bolus propulsion in the oral stage. In the remaining patients, the dysphagia is due to cerebrovascular disease (11%) or to pharyngeal or esophageal pathology (7%).

Laryngeal dystonia, which is a life-threatening complication of antipsychotic drug therapy, primarily with haloperidol and phenothiazines, is produced by acute spasmodic contraction of the adductor laryngeal muscles. Symptoms include respiratory distress, dysphonia, and stridor. Neuroleptic-induced bronchospasm may precede the onset of stridor. Patients typically indicate extreme subjective distress by clutching their anterior cervical area. Most patients also have other dystonias involving the head and neck, including torticollis, retrocollis, trismus, tongue protrusion, and deviation of the eyes up, down, or sideward. In general, the symptoms and signs develop in the first week after starting or rapidly increasing the dose of neuroleptic medications. Similar dystonic phenomena have been described after treatment with the antiemetics promethazine, prochlorperazine, and metoclopramide. A reduction in the dose of anticholinergic or antiparkinsonian medication used to prevent or treat extrapyramidal symptoms can also precipitate laryngeal dystonia. The condition is more common in young males and must be distinguished from epiglottitis, allergic or anaphylactic laryngeal edema or laryngospasm, mechanical obstruction, and psychogenic stridor. Intravenous administration of diphenhydramine (initial dose, 25 mg; may repeat after 5 minutes if symptoms persist) is the treatment of choice, and endotracheal intubation is seldom required.

Drug-Induced Neutropenia and Agranulocytosis

Drug-induced neutropenia with absolute neutrophil counts of less than 1500/μL has been observed during treatment with most second-generation antipsychotics (clozapine, olanzapine, risperidone, and quetiapine) and mood stabilizers (carbamazepine, valproic acid, and lamotrigine) as well as some antidepressant drugs (tricyclic antidepressants and mirtazapine). Clozapine-induced neutropenia occurs in 4 to 5% of patients within 6 months after starting treatment and progresses to agranulocytosis in 10% or more of neutropenic patients if the drug is continued. In vitro, clozapine toxicity requires peroxide and peroxidase, and the defect in oxidation is related to abnormalities in the *NQO2* (quinone oxidoreductase) gene involved in drug

TABLE 442-2 DIFFERENTIAL DIAGNOSIS OF NEUROLEPTIC MALIGNANT SYNDROME

Infection of the central nervous system
Infection in patients with drug-induced parkinsonism
Drug overdose (psychostimulants, antidepressants, lithium, anticholinergics)
Alcohol or drug withdrawal (benzodiazepines, barbiturates, antiparkinsonian drugs)
Side effects of nonpsychotropic dopamine-depleting drugs (reserpine, metoclopramide, prochlorperazine, promethazine)
Cholinergic rebound
Serotonin syndrome
Thyrotoxicosis
Malignant hyperthermia

TABLE 442-3 CLASSES OF MEDICATIONS THAT PRODUCE SEROTONIN SYNDROME IN PSYCHIATRIC PATIENTS

Selective serotonin reuptake inhibitors
Monoamine oxidase inhibitors
Atypical antipsychotics
Heterocyclic antidepressants
Trazodone
Dual-uptake inhibitors
Psychostimulants
Buspirone
Mood stabilizers
Analgesics
Antiemetics
Cough suppressants
Dietary supplements

detoxification. Treatment with clozapine should be started only if the baseline absolute neutrophil count is greater than 1500/μL. The concomitant use of carbamazepine, angiotensin-converting enzyme inhibitors, sulfonamides, and propylthiouracil, and mirtazapine should be avoided because they can produce neutropenia and increase the risk for agranulocytosis. Clozapine should be stopped and the patient evaluated immediately for fever, oral ulcerations, and symptoms or signs of infection. Complete blood counts should be obtained once a week for the first 26 weeks and every other week thereafter, and clozapine should be stopped and all medications reassessed if the absolute neutrophil count drops below 1500/μL. Clozapine-related agranulocytosis has been treated successfully with colony-stimulating factors (either granulocyte or granulocyte-macrophage colony-stimulating factor).

Neutropenia has also been associated with olanzapine, risperidone, and quetiapine in patients who have never received clozapine. Treatment with anticonvulsant mood stabilizers, particularly carbamazepine, is associated with a dose-dependent neutropenia and thrombocytopenia in approximately 10% of patients in the first 6 months of treatment and should be monitored with complete blood counts twice each month during this period.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome, which occurs in approximately 0.2% of patients receiving neuroleptics, must be part of the differential diagnosis of fever and rhabdomyolysis (Chapter 115) in a psychiatric patient (Table 442-2). The frequency is greater in young males and patients who are malnourished or dehydrated, have Parkinson's disease, or are treated parenterally with large doses of neuroleptics over short periods. The main diagnostic criteria are elevated temperature (higher than 104° F [40° C] in 40% of patients) and diffuse muscle rigidity (ranging from mild hypertonicity to severe "lead pipe" stiffness). In addition, two or more of the following are required for a definitive diagnosis: (1) autonomic instability (tachycardia, elevated or labile blood pressure, postural hypotension, diaphoresis, sialorrhea, and urinary incontinence), (2) changes in mental status (ranging from confusion to mutism or coma), (3) leukocytosis (up to 20,000/mL), and (4) elevated creatine kinase (up to 100,000 IU/L). Other clinical manifestations include bradykinesia, chorea, dystonias, dysphagia, dysarthria or aphonia, seizures, and tremor. The severity of rhabdomyolysis correlates with the creatine kinase level and with the presence of myoglobinemia, myoglobinuria, metabolic acidosis, and azotemia. The electroencephalogram shows nonspecific slowing in slightly more than half of patients.

The time lag from starting the drug to the onset of neuroleptic malignant syndrome is generally short, with 30% of cases developing within 48 hours and 96% within the first month of treatment. The exception appears to be clozapine-associated neuroleptic malignant syndrome, which has an average time lag of 50 days. Neuroleptic syndrome is sometimes confused with severe catatonia (Chapter 404), but the catatonic signs in neuroleptic malignant syndrome are usually restricted to mutism and akinesia. Furthermore, hyperthermia, rigidity, tremor, and rhabdomyolysis are not present in patients with catatonia. Nonetheless, close medical follow-up of severely catatonic patients is warranted because they are at very high risk (22%) for neuroleptic malignant syndrome.

Untreated, neuroleptic malignant syndrome has a mortality rate of 10% as a result of acute renal failure, aspiration pneumonia, adult respiratory distress syndrome, disseminated intravascular coagulation, and cerebellar neuronal degeneration. Most fatalities are avoidable if the diagnosis is made early, the neuroleptic agent is discontinued rapidly, and the patient is immediately transferred to an intensive care setting for supportive and specific therapy. Bromocriptine (2.5 mg three times daily orally or through a nasogastric tube; may increase by 2.5 mg three times daily to a maximal daily dose of 40 mg) or amantadine (100 mg orally or through a nasogastric tube twice daily; may increase to 300 mg/day in divided doses) should be used in moderately severe cases and continued until the muscle rigidity and metabolic abnormalities have significantly improved. The skeletal muscle relaxant dantrolene (starting with a dose of 1 mg/kg intravenously and titrated to a maximal dose of 10 mg/kg/day divided into three intravenous or oral doses) should be added to bromocriptine or amantadine in patients with fulminant hypermetabolic features and those with persistent muscle rigidity despite treatment with dopamine agonists. Refractory neuroleptic malignant syndrome improves after electroconvulsive therapy (ECT).

Serotonin Syndrome

Serotonin syndrome (Chapter 440) is an adverse drug reaction primarily produced by excess serotonergic agonism of central nervous system and peripheral serotonin receptors by selected drugs (Table 442-3). In postmarketing surveillance studies of the newer antidepressants, the syndrome has an incidence of 4 cases per 10,000 patient months in patients who start taking nefazodone, a drug that inhibits neuronal uptake of serotonin and norepinephrine and also acts as a 5-HT2 receptor antagonist. The syndrome also occurs in 15% of patients with intentional overdose of selective serotonin reuptake inhibitors (SSRIs). The serotonin syndrome is caused by overstimulation of 5-HT1A and possibly also 5-HT2 receptors through excess of serotonin precursors or agonists, increased serotonin release, reduced serotonin uptake, and decreased serotonin metabolism. Severe cases of the syndrome have been more frequently reported in patients treated with monoamine oxidase inhibitors who took over-the-counter dextromethorphan or the illegal methylenedioxymethamphetamine (Ecstasy) or who started treatment with serotonin reuptake inhibitors, meperidine, or atypical antipsychotics such as aripiprazole.

Potentially life-threatening, the syndrome is characterized by changes in mental status (ranging from agitation to confusion and coma), autonomic instability (tachycardia, labile or high blood pressure, diaphoresis, and diarrhea), neuromuscular abnormalities (myoclonus, mydriasis, ocular clonus, rigidity, hyperreflexia, tremors, and shivering), and hyperthermia. The symptoms occur within the first 24 hours and sometimes within minutes after the initial use of medication, a change in dose, addition of a new drug, or overdose attempt. Death may occur as a consequence of rhabdomyolysis with renal failure, hyperkalemia, disseminated intravascular coagulation, and acute respiratory distress syndrome. The differential diagnosis includes neuroleptic malignant syndrome, viral or bacterial meningitis or encephalitis, heat stroke (Chapter 109), anticholinergic toxidrome (Chapter 110), and drug (Chapter 33) or alcohol withdrawal (Chapter 32).

General management includes immediate discontinuation of serotonergic drugs, comprehensive supportive therapy, and benzodiazepines for control of agitation and myoclonus. Specific therapy relies on the use of cyproheptadine

(an H_1-receptor antagonist with antiserotonergic and anticholinergic properties) and chlorpromazine (a 5-HT1A and 5-HT2 receptor antagonist). Cyproheptadine should be started at a dose of 12 mg administered orally or through a nasogastric tube, with additional 2-mg doses given every 2 hours until symptoms improve or the maximal dose of 32 mg has been reached. The usual maintenance dose of cyproheptadine is 8 mg three times daily. Chlorpromazine (50 mg intramuscularly; may repeat three or four times daily and increase gradually to 400 mg/day in divided doses) is indicated in patients with severe symptoms who must be treated parenterally. Rapid improvement has also been observed after single doses of olanzapine (10 mg administered sublingually). Chlorpromazine and olanzapine should be used only after the possibility of neuroleptic malignant syndrome has been excluded.

Antipsychotic-Induced Hyperprolactinemia

Drug-induced hyperprolactinemia is produced by first-generation antipsychotic medications and by risperidone, but it is quite rare with other atypical antipsychotics such as aripiprazole, olanzapine, and ziprasidone. In patients treated with prolactin-raising antipsychotic medications, hormone levels are above the normal limit in 60% of females and 40% of males. Symptomatic hyperprolactinemia (Chapter 231) occurs in about one third of these patients and is generally associated with a 10-fold increase above baseline levels. Excess prolactin leads to dysfunction of target tissues (galactorrhea, oligomenorrhea and amenorrhea, infertility, sexual impairment, and gynecomastia) as well as an increased risk for breast cancer, osteoporosis, and cardiovascular disease. The mechanism of antipsychotic-related hyperprolactinemia is suppression of dopamine inhibition of lactotroph cells in the hypothalamus. Brain imaging is required in symptomatic patients and those with significant elevated prolactin levels to exclude tumors of the pituitary and hypothalamus.

Psychogenic Polydipsia and Drug-Induced Hyponatremia

Hyponatremia is common in psychiatric patients and can lead to severe complications, including seizure, coma, brain stem herniation, and death (Chapter 118). The diagnosis is often delayed because traditional manifestations of hyponatremia, such as lethargy, restlessness, weakness, and disorientation, overlap with features of psychiatric disorders. The differential diagnosis in psychiatric settings must emphasize psychogenic polydipsia and the drug-induced syndrome of inappropriate secretion of antidiuretic hormone (SIADH) (Chapter 118).

Patients with psychogenic polydipsia typically have serum hypoosmolality and a maximally dilute urine (urine osmolality <100 mOsm/L). The incidence of polydipsia is 20% and the incidence of water intoxication is 5% in inpatient psychiatric facilities. Urinary incontinence and nocturnal enuresis may be part of the clinical manifestation. The mechanism of increased thirst is poorly understood but may involve incomplete suppression of antidiuretic hormone (ADH) by the hypothalamus as well as response to the mouth dryness produced by the anticholinergic effect of many psychotropic drugs. The differential diagnosis includes diuretic effect, renal insufficiency, glucocorticoid deficiency, and hypothyroidism. Stringent measures to restrict fluid intake are generally effective in patients with moderate hyponatremia, and clozapine limits polydipsia and improves water intoxication in refractory cases.

Drug-induced SIADH is predominantly related to SSRIs, and animal experiments have suggested that the excess serotonin stimulates release of ADH and will lead to hyponatremia, provided that water intake is sufficient. Other drugs that are commonly used by psychiatric patients and that may produce SIADH include tricyclic antidepressants, monoamine oxidase inhibitors, carbamazepine, conventional and second-generation antipsychotics, benzodiazepines, methadone, and nicotine. Elderly patients, patients with a lower body mass index, and those with a baseline plasma sodium level of less than 138 mEq/L are at higher risk. The median time to diagnosis after starting SSRIs is 9 days. Urinary excretion of sodium usually is greater than 20 mEq/L, and urine osmolality is higher than 300 mOsm/L. In patients with mild asymptomatic hyponatremia, SSRIs can be continued with careful monitoring while the patient is placed on supervised fluid restriction. For patients who cannot tolerate fluid restriction or have symptomatic hyponatremia with serum sodium levels of less than 125 mEq/L, the use of tolvaptan (initially 15 mg, titratable to 30 or 60 mg), a vasopressin V2-receptor antagonist, is effective.[3]

Risk Assessment before Electroconvulsive Therapy

ECT is highly effective for the treatment of drug-refractory major depression and other psychiatric disorders. The procedure requires a brief period of general anesthesia with sodium pentothal, etomidate, or propofol, as well as muscle paralysis with succinylcholine, during which the patient receives bag-valve-mask ventilation with supplemental oxygen and is monitored with continuous electrocardiography and pulse oximetry. Bronchospasm may follow induction of anesthesia, particularly in patients already at risk for respiratory compromise. During electrical stimulation of the brain, parasympathetic activation can lead to bradycardia or several seconds of asystole, which can be avoided by premedicating the patient with intravenous glycopyrrolate. The parasympathetic effect lasts until onset of the akinetic seizure, when sympathetic tone increases and produces tachycardia, an elevation in blood pressure, and increased myocardial demand for oxygen. These changes can be corrected with intravenous esmolol. At the same time, because of the enhanced neuronal metabolic rate, augmented blood flow to the brain increases intracranial pressure. This elevated sympathetic tone causes ECT-related myocardial ischemia, tachyarrhythmias, and potential rupture of aortic or intracranial aneurysms. The elevated intracranial pressure may lead to brain herniation in patients with a space-occupying lesion. Older patients have a high rate of prolonged confusion, arrhythmias, and falls after ECT. A structured medical evaluation before ECT can address risks and the potential for complications (Fig. 442-1). All effort must be made to optimize the patient's active medical conditions before ECT. For high-risk patients, one must require that ECT be performed in a setting that allows immediate access to an intensive care unit rather than in the ECT suite of a self-standing psychiatric hospital. Essential medications should be administered with a small amount of fluid 6 hours before ECT. Drugs that can increase or decrease the seizure threshold, such as lidocaine, theophylline, phenothiazine, tricyclic antidepressants, and benzodiazepines, must be discontinued

STRUCTURE AND FUNCTION OF THE SKIN

DAVID A. NORRIS

KEY FUNCTIONS OF THE SKIN

The skin, which is the largest organ in the body, is a tough, resilient barrier that covers the body and shields the muscle compartment and internal structures. The structure of the skin varies considerably from one area of the body to another, including changes in the thickness of its components and in its specialized structures of epithelial origin (e.g., hair, nails, sweat glands, and sebaceous glands). The skin is commonly affected in diseases, and it is often damaged by external stimuli such as radiation, sunlight, toxins, irritants, allergens, and infectious agents.

The skin serves critical functions:

- *Protection.* Melanin pigment and antioxidant enzymes are positioned in the epidermis to protect the skin against radiation. The thick reticular dermis is a barrier to injury and trauma as well as a cushion for underlying structures. The epidermis resists friction and tangential stress. The stratum corneum, which is an impenetrable barrier to external substances, is thickened on the palms and soles to provide padding and protection.
- *Thermoregulation.* Evaporation from eccrine sweat glands is critical for thermoregulation. Vascular dilation and constriction help regulate the exchange of heat in the skin to preserve heat in cold climates and eliminate heat after exercise.
- *Immunologic response.* The skin is the outermost arm of the immune response and is designed to defend against infection, transformed cells, and toxins by means of highly developed innate and acquired local immune responses.
- *Barrier to water loss.* The stratum corneum is the critical component of normal skin that prevents transepidermal water loss.
- *Secretion of wastes.* Eccrine and apocrine sweat glands transport wastes and also provide excretion of odiferous substances.
- *Sensation.* The skin is the largest sensory organ. The skin and mucous membranes are the principal sites of pleasurable sensation and also sites of unpleasant sensations.

STRUCTURE OF THE SKIN

The skin consists of two distinct layers: the *epidermis* and the *dermis* (Fig. 443-1). The skin is derived from two germinal cell lineages: the ectoderm, which gives rise to the epidermis; and the mesenchyme, which produces the dermis. These two layers are joined at a basement membrane zone termed the *basal lamina.*

The epidermis, which is a stratified squamous epithelial layer, contains several different levels of structure and function. It is held together by distinctive adhesion structures termed *desmosomes* (Fig. 443-2). The *stratum corneum*, which is the product of the dying epidermis, resists the penetration of external organisms and toxins and prevents water loss. The *basal lamina* is a very complex structure of epidermal- and dermal-derived proteins that attach the epidermis to the dermis and resist shear stress.

The *papillary dermis* is a collagenous matrix containing the blood vessels that feed the epidermis. The *reticular dermis* is a tougher cushion protecting underlying tissue and containing the epidermal adnexal structures. The blood vessels and nerves are separated into a superficial plexus in the papillary dermis and a deeper plexus that serves the adnexal structures. The dermis is separated from the fascia and underlying muscle by a layer of subcutaneous adipose tissue that allows the skin to move freely relative to deeper internal structures.

The epidermally derived adnexal structures (eccrine sweat glands, apocrine sweat glands, sebaceous glands, and hair follicles) are anchored in the dermis but penetrate the epidermis and the barrier of the stratum corneum (see Fig. 443-1). The hair follicle is a cycling structure containing specialized populations of epithelial cells, pigment cells, and mesenchymal cells that control the hair cycle. Eccrine sweat glands discharge sweat directly through the stratum corneum. Apocrine sweat glands discharge their products into hair follicles. Sebaceous glands drain into sebaceous hair follicles on the scalp, face, chest, back, axilla, and groin. An extensive network of blood vessels and nerves serves the skin. The superficial vascular plexus feeds the epidermis through an extensive complex of capillary loops in the papillary dermis. The deep vascular and nerve plexus serve the adnexal structures in the dermis. The hair follicles, with their apocrine and sebaceous glands, and the eccrine sweat glands are potential avenues for transepidermal absorption of drugs because they penetrate the stratum corneum.

Cells of the Epidermis and Epidermal Differentiation

The epidermis is a stratified squamous epithelium composed mostly of keratinocytes, with other resident cells in distinct locations (melanocytes, Langerhans cells, and Merkel cells). In response to various stimuli, migrating cells such as lymphocytes, dermal macrophages, neutrophils, and eosinophils enter the epidermis. Keratinocytes are attached firmly to each other through desmosomes (see Fig. 443-2), which connect to the rigid keratin intermediate filament network and give the epidermis strength. The basal layer of the rigid epidermis connects to the basement membrane zone by means of hemidesmosomes, which are highly organized adhesion structures linked to the basal keratin network. Adherens junctions link surrounding keratinocytes and connect them to the actin microfilament network. These junctions provide more plastic adhesions that are also involved in actin-mediated movement, and the dendritic structure of melanocytes and Langerhans cells depend on attachment of these cells to keratinocytes through E-cadherin-containing adherens junctions.

Keratinocytes and Epidermal Differentiation

Epidermal Differentiation

Epidermal differentiation is a genetically programmed process by which keratinocytes differentiate from proliferating cells in the germinative layer to form tightly attached "prickle" cells in the malpighian layer, dying cells in the granular layer, and corneocytes in the stratum. During this process, keratinocytes undergo tremendous changes reflecting their different functional characteristics. Keratinocytes are named for the intermediate filament protein keratin, which forms insoluble stiff filaments that give the epidermis its strength. The keratins are made of tetramers composed of two basic and two acidic keratins (K5/14 in the basal layer, K1/10 in the spinous layer, K6/16 in the hyperproliferative epidermis, K9/19 in the palms and soles). Keratin has versatile properties and is the major component of hair and nails in humans and of beaks, hooves, and feathers in other animals.

The attachments within the epidermis are formed by desmosomes and adherens junctions. The adherens junctions that form between keratinocytes are characterized by homophilic binding of cell surface cadherins and by binding of the adhesion structure to actin microfilaments within the cell by catenins (Fig. 443-3A). Desmosomes are composed of molecules called desmogleins and desmocollins, which are homologous to cadherins and form adhesion structures with keratins through numerous associated proteins such as plakoglobin and plakophilin (see Fig. 443-3B). The basal keratinocytes are attached to the basal lamina at the hemidesmosome, a specialized adhesion structure linked to the basal cell keratin filament network (see Fig. 443-3C). The progressive differentiation of the epidermis is associated with specific changes in protein expression and function.

Functions of the Epidermal Layers

The *germinative* (*basal*) *layer* of the epidermis is responsible for cell proliferation. This layer is resistant to apoptosis because of defenses maintained by receptors for growth factors and matrix molecules. The germinative layer can become a migrating epithelial tongue to aid in wound healing.

The *spinous layer* produces a dense keratin filament network (keratins 1/10) that interacts with desmosomes, and it synthesizes involucrin (which is involved in protein cross-linking with the plasma membrane in the granular layer), a protective antioxidant network (glutathione reductase, peroxidases, catalases), cytokines, chemokines, lamellar bodies, and keratohyaline granules.

Cells in the *granular layer* undergo programmed cell death (apoptosis). Keratohyaline granule profilaggrin is activated into filaggrin, thereby inducing keratin cross-linking. Lamellar body contents are secreted into the extracellular space by fusion of the lamellar body to the cell membrane. Cross-linking of involucrin and cornifin to the cell membrane by transglutaminase produces a thickened, cornified envelope. Protein synthesis ceases as

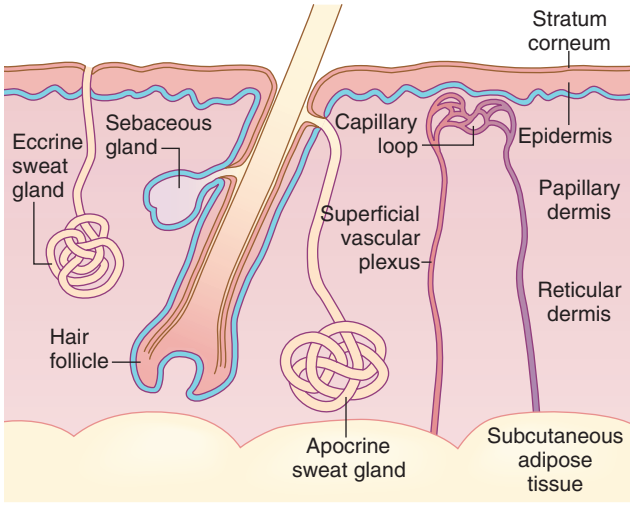

FIGURE 443-1. The skin and adnexal structures. The relationship of the epidermis and its adnexal structures (sebaceous and sweat glands and hair follicles) to the dermis and subcutaneous adipose tissue is shown. Note how these structures are associated with breaks in the barrier of the stratum corneum.

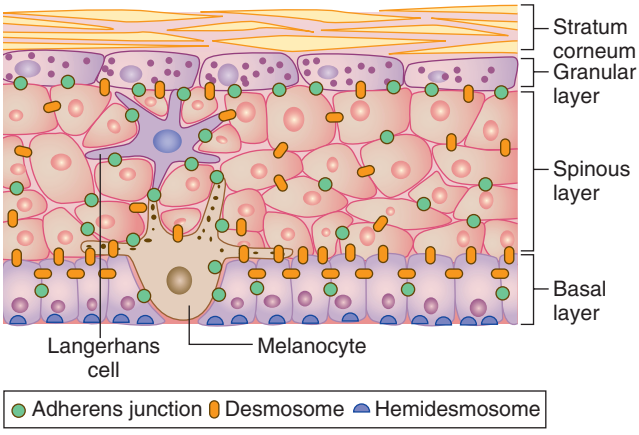

FIGURE 443-2. Cell attachment in the epidermis. The epidermal keratinocytes, melanocytes, and Langerhans cells form a network of attachments crucial to normal epidermal function.

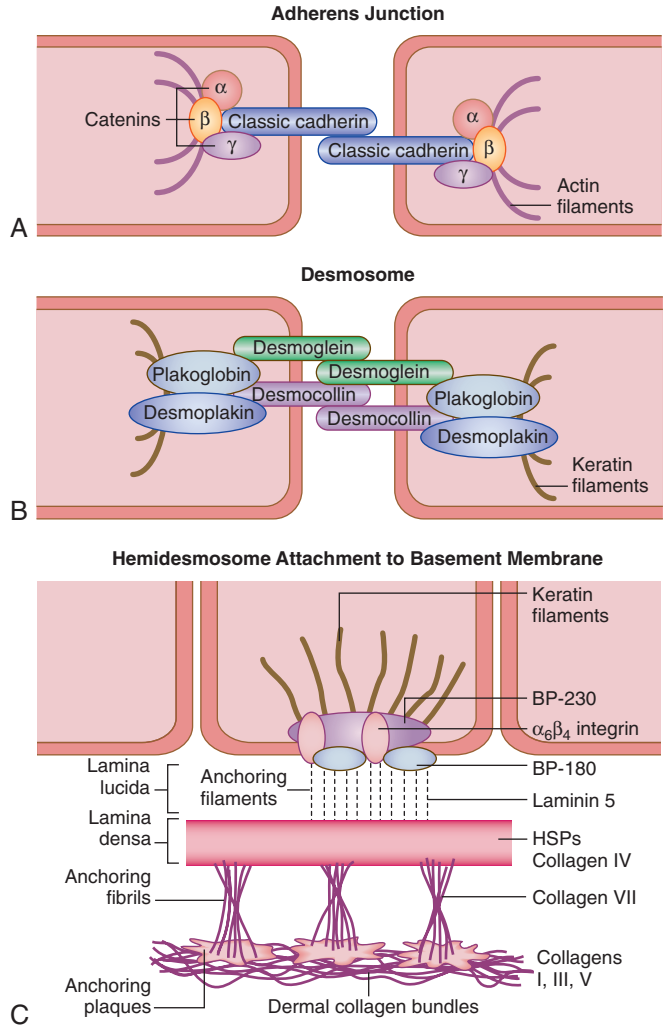

FIGURE 443-3. Molecular aspects of key epidermal adhesion structures and connection of the epidermis to the dermis. A-C, These structures are crucial to the normal integrity of the skin. Mutations or autoimmune damage to these structures has devastating effects on skin function. HSP = heat shock protein.

cells die to form intact corneocytes, which contain cross-linked keratin filaments and a thick cornified envelope.

Flat corneocytes surrounded by phospholipid lamellae form the impervious *stratum corneum*. Although the cornified layer provides a thin, flexible barrier to protect sensitive cells from the external environment, some molecules can diffuse through the cornified layer. Indeed, this transepidermal route is the major route of penetration of topical medications (Chapter 445). After a defined period, desquamation of superficial corneocytes occurs by enzymatic degradation of extracellular material.

Melanocytes

Melanocytes, which are dendritic cells that synthesize and secrete the pigment melanin, are derived from neural crest cells and typically migrate to the epidermal-dermal junction during embryonic development, although a few can be found in the dermis. Melanocytes are localized in the basal layer of the epidermis, with the ratio of melanocytes to keratinocytes ranging from about 1:4 to about 1:10 at different locations in the skin. The relative number of melanocytes is roughly the same for both genders and for all races, approximately 1500 melanocytes per square millimeter of skin surface. A totally separate population of melanocytes resides in hair follicles that produce pigmented hairs. Differences in the coloration of skin are therefore determined by the relative activity of these cells, not their numbers. Epidermal melanocytes are attached to the basal lamina by integrin receptors, and they are attached to surrounding keratinocytes by E-cadherin–mediated attachments. Melanin pigment is synthesized in melanocyte-specific organelles termed *melanosomes*. Melanosome transfer is achieved when keratinocytes actively engulf the melanosome-containing cytoplasmic tips of the dendritic processes of the melanocytes. Exposure to ultraviolet (UV) light increases the rate of formation of melanosomes and enhances their rate of delivery to keratinocytes.

Melanin is a complex heteropolymer that absorbs light across the entire UV and visible spectrum; it provides the most effective protection of the skin against solar radiation. Melanization is a complex biochemical process controlled largely by three genes: tyrosinase (rate-limiting step), which oxidizes tyrosine to 3,4-dihydroxyphenylalanine (dopa); tyrosinase-related protein 1 (TyRP-1); and tyrosinase-related protein 2 (TyRP-2). Control of melanization is a complex genetic and environmental process involving more than 150 genes. One important level of control is binding of melanocyte-stimulating hormone to the melanocortin-1 receptor (MC-1R) on melanocytes. The enzymes that control melanization are transported into the melanosome, where the biochemical processes occur in a protected organelle-bound environment. The whole organelle is then transported to keratinocytes, where it resides in a "helmet" location above the nucleus. Polymorphisms in MC-1R control the relative amounts of the three key enzymes. Decreases in TyRP-1 and TyRP-2 lead to the production of pheomelanin, a brown-red pigment with inferior photoprotective properties. This type of pigment is seen in red-haired individuals and is associated with decreased sun protection, increased photoaging, and a higher rate of melanoma and nonmelanoma skin cancer. UV light can transform melanocytes into malignant melanoma, the most deadly form of skin cancer (Chapter 210).

Melanocytes are terminally differentiated cells with no stem cell population to repopulate interfollicular melanocytes. A melanocyte precursor population in the outer root sheath of the hair follicle can be mobilized to repopulate lost interfollicular melanocytes—an approach to repigmentation

that is used to treat human vitiligo. However, melanocyte stem cell populations are believed to exist in the hair follicle, where they replenish the melanocytes of the hair bulb during each cycle of hair regeneration in the transition from telogen to anagen (see Hair).

Langerhans Cells

Dendritic Langerhans cells are an important subset of antigen-presenting cells located in the midportion of the epidermis. These cells become more abundant at sites of inflammatory skin disorders, including allergic reactions such as contact dermatitis (Chapter 446). Langerhans cells are migratory, and they contain characteristic striated, rodlike structures known as Birbeck granules. They also bear several important immunologic cell surface receptors (DC1, major histocompatibility complex [MHC] class II, immunoglobulin G [IgG] receptor, C3 receptor). In contact sensitization (contact dermatitis), Langerhans cells internalize and process antigen, migrate to regional lymph nodes, and present the antigen to naïve lymphocytes. When the antigen is reapplied to skin (challenge), the Langerhans cells again process and present the antigen to sensitized lymphocytes in the skin or in lymph nodes.

Merkel Cells

Merkel cells are scattered among the basal keratinocytes and are often found near or in contact with very fine, unmyelinated nerves, with which they form synapses. Merkel cells are present singly or in clusters called tactile corpuscles. They are attached to adjacent epidermal cells by numerous desmosome connections, but their tonofilaments, unlike those of keratinocytes, are not grouped into bundles. In the cytoplasm of Merkel cells are numerous membrane-bound dense granules that contain catecholamines. It is believed that Merkel cells serve as adapting mechanoreceptors. Merkel cell tumors are uncommon but are among the most deadly of skin cancers.

Dermal-Epidermal Junction

The dermal-epidermal junction is a transitional zone in which the basal layer of the epithelium is connected to penetrating deep collagenous anchors that originate in the papillary dermis. The connection is composed of collagenous rods, globular domains, and cruciate protein complexes that form a firm attachment that resists friction and tangential stress. This junction, which is the weakest structure point in the skin, is the site of blistering induced by cold, heat, and immunologically and genetically mediated blistering disorders.

Downgrowths of the epidermis form tiny ridges, called rete pegs, that add bonding surface area between the dermis and epidermis. The sandwiched basal lamina follows the ridges, which are more pronounced in areas of high abrasion. The lamina has three zones: the lamina lucida, the lamina densa, and the fibroreticular lamina. Keratin filaments in the basal cells anchor in the hemidesmosomes, which connect to anchoring filaments of the lamina lucida and then to the dense collagen and heparan sulfate proteoglycan matrix of the lamina densa. Anchoring fibrils of type VII collagen form the fibroreticular lamina and end in the anchoring plaques that intercalate with type III and VI collagen in the papillary dermis.

Dermis

The thickness of the dermis varies considerably in different parts of the body. For descriptive purposes, the dermis is divided into the papillary layer, which is the thinner layer next to the epidermis, and the reticular layer, which is composed of denser connective tissue and constitutes the bulk of the dermis. The papillary layer, which forms the dermal papillary ridges, is composed of collagen and reticular and elastic fibers that are woven into a loose network. The dermis contains many different cell types, including fibroblasts, fibrocytes, macrophages, leukocytes, and plasma cells. The vascular supply to the skin is confined to the dermis, where small arteries enter from the subcutaneous tissue and form deep and superficial sheetlike plexus. Capillary loops ascend into the dermal papillae and return through the venous plexus. The postcapillary venule portion of the vascular network, which is where leukocytes enter the tissue, is an important target of damage in allergic vasculitis. The nerve supply to the skin is very extensive and consists of both myelinated and nonmyelinated fibers. Specialized sensory structures such as pacinian and Meissner's corpuscles are located prominently in the hands and feet. Because up to 4 to 5% of the total blood volume can be stored in the dermis, it plays an important role in thermal regulation; sympathetic nerve fibers control blood flow to and from the skin.

Epidermal Appendages of the Skin

Sebaceous Glands

Sebaceous glands, or oil glands, are found throughout the dermis except for the palms of the hands and the soles of the feet. Most of these glands, which are greatly activated at the onset of puberty, discharge their contents through a single duct into the lumen of hair follicles. Where these glands occur independently of hairs (e.g., the glans penis, lips, labia minora, and eyelids), they open directly onto the surface of the skin. Sebaceous secretions contain triglycerides, waxy esters, squalene, cholesterol, and fatty acids.

Eccrine Sweat Glands

Eccrine sweat glands are positioned over the entire skin but are concentrated most densely in the palms, the soles, and the head. Eccrine sweat glands, which number about 3 million, are innervated by postganglionic, cholinergic sympathetic nerves. Excess heat causes sweating to begin on the forehead and to spread elsewhere over the body. Eccrine sweat glands secrete a watery solution that is high in sodium chloride but also contains urea, uric acid, potassium, and immunoglobulins.

Apocrine Sweat Glands

Apocrine glands are scent glands whose secretion is increased by fear, sexual excitement, and other forms of heightened tension. Apocrine glands are present in the axilla, the external genitalia, the areolar skin around nipples, and the perianal area, and they develop following the onset of puberty. Specialized apocrine glands include Moll's glands on the eyelid and ceruminous (wax) glands in the auditory canal.

Nails

The nail is composed of a proximal germinative epithelium that is called the nail matrix, a keratinized product that is called the nail plate or body, an underlying specialized epithelium that is called the nail bed and is attached to the undersurface of the nail, and a protective loop of skin that is called the proximal nail fold. Underlying the proximal part of the body of the nail is a collection of germinal cells that form an opaque spot on the nail, the lunula. The lunula is the site of the proliferating nail matrix that is responsible for growth of the nail.

Hair

There are three types of hair follicles: vellus hair follicles located over most of the body; terminal hair follicles located on the scalp, beard area, axilla, groin, and other hairy areas; and sebaceous hair follicles located on the scalp, face, beard, chest, back, axilla, and groin. Sebaceous hair follicles have a minimal hair shaft but hypertrophied sebaceous glands. Terminal hairs form the long hairs of the scalp and beard. The hair follicles of the eyelashes and eyebrows also have specialized characteristics determined by local mesenchymal factors.

Hairs are dead shafts composed of fused plates of keratin that project from the surface of the epidermis. Hair does not grow continuously but rather passes through a cycle (Fig. 443-4). Anagen is the growth phase. Then comes a short catagen stage in which portions of the hair follicle involute and growth ceases. Next is the telogen, or resting, phase. After a telogen phase of 3 to 4 months, a new anagen hair develops from the follicular stem cells, and the existing hair falls out or is easily pulled out. The hair cycle depends on synchronized cooperation among four major components of the hair follicle: the dermal papilla, the hair matrix, the outer root sheaths, and the stem cells in the bulge region. During the actively growing anagen phase of the hair cycle, signals from the dermal papilla maintain the proliferating hair matrix. When these signals terminate, the follicle enters the catagen phase in which the matrix and root sheaths of the lower follicle die by apoptosis. The follicle then enters a resting telogen phase. When the follicle re-enters the anagen phase, signals from the dermal papilla stimulate stem cells in the bulge region of the follicle, and these cells migrate to form the new matrix, initiate a new hair shaft, and cause the old hair to fall out. In normal follicles in young healthy adults, the anagen phase is almost 3 years, and the telogen phase is about 3 months. At any time, 10 to 15% of the hairs are in telogen on a healthy young scalp.

In telogen effluvium, the shift to telogen is abrupt, and hairs fall from the scalp precipitously in 3 months when new anagen hairs are formed in the follicles. This pattern is commonly seen 3 to 4 months after a severe systemic illness or at the termination of pregnancy. A gradual shift to the telogen phase occurs with age and is even greater in androgenetic alopecia.

SPECIALIZED ASPECTS OF SKIN STRUCTURE AND FUNCTION

Skin-Associated Immune System

The skin is the most external component of the immune response, with well-developed elements of both the innate and acquired immune systems (Chapter 44). The barrier of the stratum corneum is broken by adnexal structures such as hair and sweat glands, and infections in these sites are suppressed by a network of innate immune responses and defenses. The skin is also a principal site for invasion by bacteria, parasites, and viruses, and it is an important site of tumor induction; all these processes are influenced by a well-developed acquired immune response. The skin contains several populations of antigen-presenting cells, including the epidermal Langerhans cells. Trafficking of T cells to the skin occurs through skin-specific homing receptors such as the cutaneous lymphocyte antigen.

The skin's innate immune system includes macrophages, dendritic cells, and neutrophils as well as a very extensive epidermal network of cytokines (e.g., interleukin-1 [IL-1] and tumor necrosis factor-α [TNF-α]) and chemokines. The skin has a number of receptors for foreign organisms (CD14, toll-like receptors, mannose receptors), defensins and other antimicrobial peptides, and networks that augment and inhibit complement in the papillary dermis.

The skin's acquired immune system includes an epidermal network of specialized dendritic cells (Langerhans cells) plus dermal dendritic cells. The cutaneous lymphocyte antigen stimulates the trafficking of lymphocytes to the skin. Both T_H1 and T_H2 responses are well developed in skin, but most inflammatory skin diseases have a T_H1 response. Hair follicles may be immunologically privileged sites because they lack MHC class I.

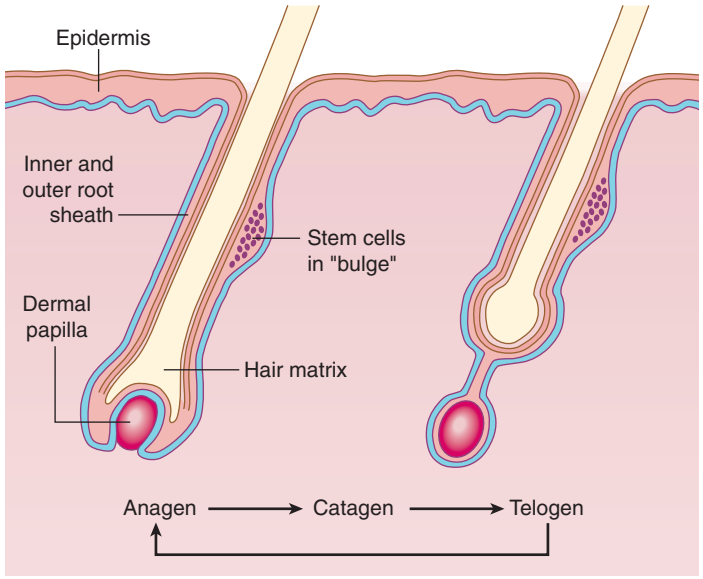

FIGURE 443-4. Hair follicle cycle. Communications among the dermal papilla, the matrix, the follicle sheath, and the stem cells control the hair cycle through its anagen, catagen, and telogen phases.

Control of Apoptosis in the Skin

Apoptosis is a normal part of the cycle of epidermal differentiation. In the granular cell layer, transglutaminase-mediated cross-linking of involucrin initiates formation of the cornified envelope, which is a specialized apoptotic envelope. Unlike other apoptotic cells, the corneocyte is not phagocytized or fragmented. Epidermal stem cells, melanocytes, and proliferating transit-amplified cells of the basal and suprabasal epidermis are resistant to apoptosis, owing to defenses against apoptosis mediated by integrin and growth factor receptor ligation. Integrin and growth factor expression are lost in the differentiating epidermal compartment, and these cells are susceptible to apoptosis induced by chemotherapy, activation of death receptors such as Fas, and UV radiation (Fig. 443-5). In the granular cell layer, apoptosis initiates terminal changes in keratinocytes, thereby producing the dead corneocytes that are the "bricks" of the stratum corneum.

Endothelial cells are also resistant to apoptosis by virtue of their attachment to basement membrane proteins through integrin receptors and because of antiapoptotic proteins that are induced during inflammation to protect these cells. Conversely, during vessel remodeling, the antiapoptotic defenses decrease, and endothelial cells die.

Activated lymphocytes, Langerhans cells, and granulocytes that enter the skin are all sensitive to apoptosis. Most phototherapy protocols to treat inflammatory skin diseases rely on UV light–induced apoptosis to destroy Langerhans cells and lymphocytes, whereas the relative resistance of keratinocytes and melanocytes to UV light protects the normal underlying skin cells.

Ultraviolet Radiation and the Skin

The skin is uniquely susceptible to damage induced by exposure to radiation from the sun. Visible and UV light penetrates into the skin and produces important biologic effects. Some effects, such as photoactivation of vitamin D, are beneficial, but most are damaging.

The skin has a number of natural defenses against UV light. First, melanin, a heteropolymer that is transferred from melanocytes to keratinocytes, protects the basal keratinocytes against UV radiation. Second, antioxidant enzymes (e.g., catalase, peroxidase, thioredoxin, and superoxide dismutase) protect skin cells against oxidant damage. Macrophages are induced by UV radiation to enter the epidermis to remove damaged cells. UV radiation also induces Langerhans cells to exit the epidermis and present antigens to T cells

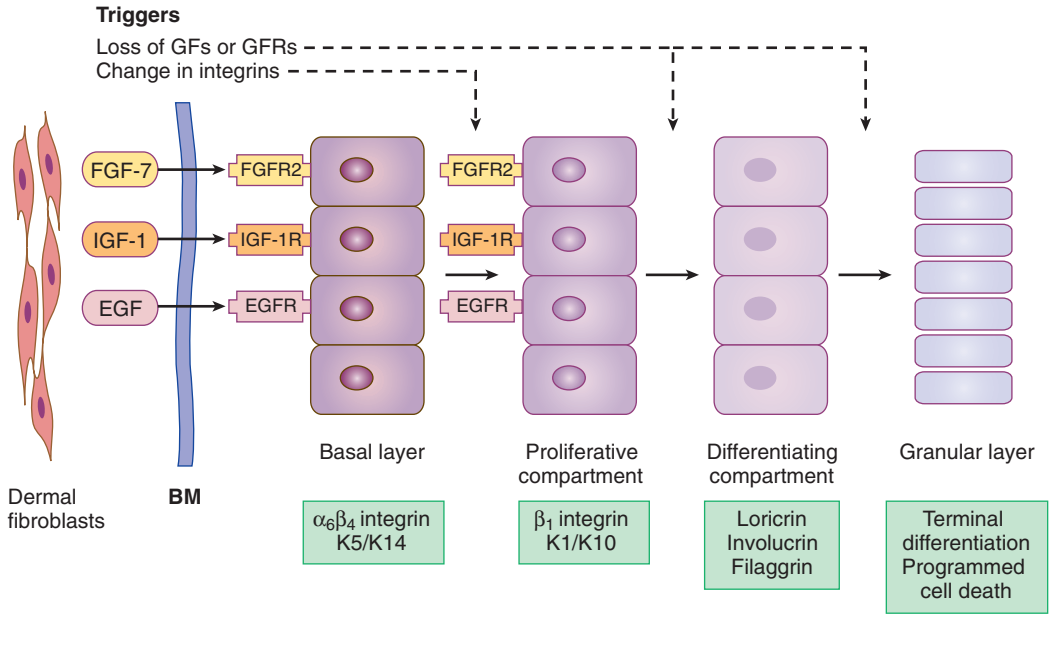

FIGURE 443-5. Epidermal differentiation. Differentiation of the epidermis, controlled by growth factor receptors and integrin receptors, also modulates the susceptibility of the epidermis to apoptosis induced by external and internal triggers. BM = basal membrane; EGF = epidermal growth factor; EGFR = EGF receptor; FGF = fibroblast growth factor; FGFR = FGF receptor; GF = growth factor; GFR = GF receptor; IGF = insulin-like growth factor.

TABLE 443-1 CLINICAL ASSOCIATIONS WITH PRURITUS

SKIN DISEASES
Dermatitis, including contact dermatitis
Bullous disorders, especially dermatitis herpetiformis and bullous pemphigoid
Drug effects (opiates, aspirin, quinidine)
Urticaria and angioedema
Lichen planus
Sunburn
Seborrheic dermatitis
Infestations (e.g., scabies, pediculosis)
Xerosis (dry skin)
Irritant particles (e.g., fiberglass, "itching powder")
SYSTEMIC DISEASES
Uremia
Obstructive biliary disease (primary biliary cirrhosis, cholestatic hepatitis, cholestasis of pregnancy, extrahepatic biliary obstruction)
Hematologic and myeloproliferative disorders (lymphoma, polycythemia vera, iron deficiency anemia)
Endocrine disorders (thyrotoxicosis, hypothyroidism, diabetes, carcinoid)
Carcinomas (breast, stomach, or lung)
Psychiatric disorders (e.g., delusional states, stress, psychosis)
Neurologic disorders (e.g., multiple sclerosis, notalgia paresthetica, neuropathy)
Mastocytosis (urticaria pigmentosum, telangiectasia macularis eruptiva perstans)

in regional lymph nodes. Finally, keratinocytes release large amounts of IL-1 and TNF-α in response to UV radiation, and a complex system of antagonists and decoy receptors buffer the epidermis from cytokine-induced damage.

Despite these defenses, UV radiation damages keratinocytes and induces malignancy. UV radiation damage also induces both local and systemic immunosuppression, and it can induce autoimmunity when apoptotic keratinocyte autoantigens are presented to lymphocytes in patients with diseases such as lupus erythematosus.

Itching

The sensations of both itch and pain are transmitted by unmyelinated C fibers. It is assumed that the receptors are the free nerve endings in the dermis and epidermis. Multiple compounds induce pruritus: amines (histamine and serotonin), proteases (papain, kallikrein, trypsin), neuropeptides (substance P, vasoactive intestinal peptide, calcitonin gene–related peptide), eicosanoids, opioids, cytokine growth factors, and products of eosinophils and platelets. Many of these compounds act through their effects as mast cell degranulators. Histamine is the major itch-inducing product of mast cells, but other mediators are also involved. Pruritus is a frequent component of many skin and systemic diseases (Table 443-1).

Pruritus is a common clinical problem whose treatment is often unsatisfactory. Treatment of any underlying skin or systemic disease is necessary for long-term success. Drugs that inhibit the effects of mast cell products (H_1- or H_2-blocking antihistamines, antileukotrienes) or that inhibit mast cell degranulation (phosphodiesterase inhibitors, β-agonists) are effective as oral agents. Common options include topical therapies (Table 443-2) and systemic therapies (Table 443-3). Neuropeptide-mediated itching can be inhibited by desensitization with capsaicin. Opiate antagonists block the central opiate receptors that induce the pruritus associated with opiate use. UV radiation treatment can effectively treat the intractable pruritus that occurs in patients with renal failure.

Wound Healing

The skin is the major target of wounding in most people and is the preeminent model used to study wound healing in animals and humans. Wound healing is a complex process with three sequential phases: inflammation, proliferation and tissue formation, and tissue remodeling. The phase of tissue remodeling extends for weeks and months after the closure of wounds, and the fibroblast is the cornerstone of remodeling of the dermis, vessels, and basement membrane.

Vascular abnormalities (arterial insufficiency, venous stasis, and microangiopathy) are commonly associated with poor wound healing. Poor wound healing is also a serious problem in patients with chronic infections or malnutrition. Patients with extensive skin disease, especially mechanobullous or immunobullous disorders such as epidermolysis bullosa or pemphigus, likewise demonstrate defects in wound healing. Efforts to promote wound healing in these situations focus on repair and reversal of vascular disease,

TABLE 443-2 TOPICAL TREATMENTS FOR PRURITUS

MEDICATION	DOSE	COMMENTS
Topical corticosteroids	Variable	Not directly antipruritic, may be useful in pruritus due to inflammatory skin dermatoses
Topical calcineurin inhibitors	Tacrolimus 0.03 and 0.1% ointment Pimecrolimus 1% cream	Particularly useful in anogenital pruritus; may cause transient burning and stinging
Doxepin	5% cream	20-25% risk for sedation
Menthol	1-3% cream or lotion	Useful in patients who report cooling as an alleviating factor
Capsaicin	0.025-0.1% cream	Particularly useful in neuropathic itch, may cause transient burning
Salicylic acid	2-6%	Useful in lichen simplex chronicus, avoid in acute inflammatory dermatoses
Local anesthetics	Pramoxine 1.0-2.5%	Useful on face and for chronic kidney disease
Cannabinoids	Creams containing *N*-palmitoylethanolamine	Useful in atopic dermatitis and chronic kidney disease

TABLE 443-3 SYSTEMIC TREATMENTS FOR PRURITUS

MEDICATION	DOSE	COMMENTS
Antihistamines	Chlorpheniramine 4 mg Loratadine 10 mg Fexofenadine 60 to 180 mg	Sedating, but no direct effect on pruritus, except in urticaria
Antidepressants		
SNRIs	Mirtazapine 7.5-15 mg orally at bedtime	Nocturnal pruritus; may increase appetite and weight
SSRIs	Paroxetine 10-40 mg orally per day	Psychiatric patients and paraneoplastic pruritus
	Fluvoxamine 25-150 mg orally per day	Psychiatric patients and paraneoplastic pruritus
	Sertraline 75-100 mg orally per day	Cholestatic pruritus
μ-Opioid receptor antagonists	Naltrexone 25-50 mg orally per day	Pruritus associated with cholestatic or chronic kidney disease; can cause nausea, vomiting, and drowsiness
Neuroleptics	Gabapentin 100-3600 mg orally per day Pregabalin 150-300 mg orally per day	Neuropathic pruritus; can cause drowsiness and weight gain
Substance P antagonist	Aprepitant 80 mg orally per day	Sézary's syndrome
Immunosuppressants	Cyclosporine 2.5-5 mg/kg orally per day	Short-term use for refractory atopic dermatitis; monitor blood pressure and renal function
	Azathioprine 1.0 to 2.5 mg/kg orally per day	Refractory atopic dermatitis; monitor for myelosuppression

SNRI = serotonin-norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

EXAMINATION OF THE SKIN AND APPROACH TO DIAGNOSING SKIN DISEASES

CHERYL A. ARMSTRONG

EXAMINATION OF THE SKIN

The examination of the skin is a critical component of the comprehensive medical approach to the patient. By learning how to examine the skin and approach the diagnosis of skin diseases, the physician can focus on the lesions that warrant therapy or provide important information about the systemic health of the patient. Other lesions may be of cosmetic concern to the patient even though they have little or no medical significance.

As the organ system that is an interface with the environment, the skin has an extensive array of mechanical, biochemical, immunologic, and neurologic properties that both inform and protect each individual. The skin also has a vast ability to alter its cellular and acellular components in response to internal or external insults, a process that leads to changes that are subsequently defined as disorders or diseases. The physical examination of the skin can provide information about both cutaneous and systemic diseases, and the examination can sometimes diagnose serious medical conditions at an otherwise asymptomatic stage.

Skin disorders can usually be visualized directly by both the patient and the physician. For example, the patient not only feels the itch and discomfort of an allergic contact dermatitis reaction to poison ivy but also sees the vesicular and crusted skin lesions. The appearance of new lesions or a sudden change in existing lesions can elicit emotional reactions in patients or their family members. The physician must learn to see the same eruptions using a careful and systematic approach that leads to a specific and treatable diagnosis.

History and Physical Examination

Most dermatologists conduct the dermatologic history and examination simultaneously. The physician can best focus the history and full skin examination by first visualizing the lesion or lesions that constitute the patient's primary skin complaint. Because there are hundreds of described dermatoses, the systematic approach is based on pattern recognition.

Physical Examination

Setting

A skin examination can be conducted in virtually any medical setting. It is most effectively performed in an office equipped with an examination table, adequate natural or artificial fluorescent lighting, examination gowns for patients to wear, and a sink for thorough handwashing before and after each examination. If natural light through a window is used, it is critical to ensure the patient's privacy inside the examination room. A movable focused artificial light beam and a lighted magnifying glass can be used to shine obliquely on the skin to assess the elevation of skin lesions. Many dermatologists prefer to examine all lesions at a 1:1 ratio without magnification, but others prefer magnifying certain types of lesions to ascertain morphologic features. For example, the follicular plugging of the lesions of discoid lupus erythematosus (Chapter 274) or the telangiectasias associated with a basal cell carcinoma (Chapters 210 and 448) may be better appreciated with magnification. Gowns that can be positioned to uncover parts of the skin surface while leaving other parts covered help ensure the patient's comfort during the examination.

Precautions

Universal precautions against infectious diseases should be practiced during every skin examination or cutaneous procedure. Handwashing with soap and warm water or the use of hand sanitizing gels or foams ensures that the physician is taking appropriate steps to avoid spreading organisms from a previous patient. As patients become more aware of the spread of infections by health care providers, it can be useful for the physician to cleanse his or her hands in the presence of the patient, rather than outside the examination room. When examining intact skin, it is not necessary to wear gloves. For the protection of both the patient and physician, gloves should be worn when the physician touches nonintact skin surfaces. Because of the increasing incidence of allergies to latex in the health care setting, the use of nonlatex gloves should be considered for all patients. Gloves should be discarded after the examination is complete or after touching the mouth or the genital area.

Total Body Examination

A total body skin examination is usually recommended for each new patient to assess existing pigmented lesions and determine whether any are serious, although there are no data to document the yield of such an approach (Chapter 14). With the steady increase in squamous cell carcinoma, basal cell carcinoma, and cutaneous melanomas over the past several decades, the total body skin examination is an opportunity to diagnose lesions in an early treatable stage as well as to educate patients about their own risk factors for developing skin cancer. Subsequently, total body skin examinations can be scheduled at 3- to 12-month intervals for patients at high risk for developing new or recurrent malignant lesions (Chapter 210), whereas patients at low risk should be examined at less frequent intervals, such as every 1 to 3 years.

Many dermatologists approach this examination by using the following sequence: face (forehead, eyelids, lips, ears, nose, cheeks, chin), neck, scalp and hair, back, chest, abdomen, arms, hands (including palms and fingernails), legs, and feet (including soles and toenails). Having the patient change into a comfortable gown with undergarments removed facilitates the ease of the examination. Some dermatologists perform part of the examination with the patient in a sitting position and part of the examination with the patient lying back on the examination table. The goal is to ensure that the skin can be well visualized and that the patient is comfortable with the amount of skin being exposed at one time.

Assessing Skin Features

Basic skin features such as skin pigmentation, skin turgor, abnormal skin color (jaundice, pallor), and the degree of photodamage to sun-exposed skin surfaces should be assessed, and these findings guide the medical history and subsequent, detailed examination. For example, patients with lightly pigmented skin and evident photodamage to the hands and face warrant a careful history to inquire about prior skin cancers in themselves and their immediate family members as well as a full body skin examination to look for precancerous or potentially malignant lesions of which the patient may be unaware. Patients with abnormal skin color, such as a yellow hue (jaundice; Chapter 149) should be questioned about known medical conditions, examined for any other cutaneous signs associated with disease of that organ, and assessed with the appropriate laboratory studies.

It is often helpful to touch the lesion and the skin surrounding the lesion. Features such as firmness, movability from the underlying skin, fluctuance, and depressibility are helpful in characterizing the lesion. Darier's sign, which is the appearance of an urticarial wheal and flare reaction after rubbing a skin lesion, is observed in lesions that contain large numbers of mast cells (e.g., urticaria pigmentosa) and is the result of the mechanical degranulation of the mast cells and the resulting release of histamine. Nikolsky's sign is dislodgement of the epidermis with the appearance of a moist, glistening defect after pushing, rubbing, or rotating normal skin near bullous lesions; this sign is typical of disorders in which epidermal cells are not well adhered together (e.g., pemphigus and toxic epidermal necrolysis).

Obtaining the History

After seeing and palpating the lesion, the physician can obtain a more detailed history and continue with a more comprehensive examination of the skin as

indicated. Pertinent questions should assess duration of the lesion or eruption, what the lesion looked like when it first began, how the lesion feels (e.g., itch, sting, tenderness, pain), and how the condition has changed since it was first noticed. It is also helpful to inquire about a history of prior similar lesions and how they progressed. A medication history is important because both systemic and topical medications can cause or exacerbate a number of skin conditions. It is also important to inquire specifically about how the patient may have tried to treat the lesion because many treatments can change the natural appearance of the lesion.

The past medical history should be targeted to obtain information about major illnesses, especially those that would lead to immunodeficiency states, as well as prior dermatologic diseases. The presence of known heritable dermatologic conditions in the family should be determined. In particular, patients should be specifically questioned about a personal or family history of atopic dermatitis, hay fever, or asthma (atopy). All patients should be asked about a personal or family history of malignant melanoma and nonmelanoma skin cancers. The social and work history can also provide critical clues to the diagnosis of a particular skin condition because many are related to occupational or recreational activities. A travel history to determine whether patients have encountered environmental stresses such as sun, heat, or cold or have been exposed to parasitic infestations can also be useful. Because psychological stress can exacerbate many dermatoses, it is useful to inquire about overall levels of anxiety and stress or recent stressful situations.

After visualizing the lesion of concern, it is often helpful to look systematically at all the skin again. It is also important to watch the patient's behavior in the examination room. Many patients think that they should not scratch lesions and they tell the physician that the lesions itch but that they do not scratch. However, direct observation shows the patient rubbing, tapping, scratching, or picking the lesion while engaged in conversation with the physician. These behaviors can change a primary lesion to a secondary lesion.

Melanoma

Patients at high risk for the development of melanoma require the most comprehensive skin examinations, commonly by a dermatologist. Photography (conventional or digital) and detailed "maps" of the nevi may be used over time to assess changes in lesions or the presence of new lesions that warrant removal. A hair dryer at the low setting can be used to blow aside the hair to allow visualization of the entire scalp. The skin of the external and internal labia is examined for pigmented lesions in women. The comprehensive skin examination is also an ideal opportunity to educate the patient about performing self-examinations that include exposed and unexposed skin including the buttocks, posterior thighs, and calves.

DIAGNOSING SKIN DISEASES

Categorization of Skin Lesions

Four major features of skin lesions or eruptions allow the skin disease to be placed in diagnostic categories that facilitate specific diagnosis: (1) the morphologic appearance of the individual lesions, (2) the distribution of lesions over the body surface, (3) the arrangement of the lesions, and (4) the number of lesions present. This information also enables the physician to determine whether the lesions are primary or secondary in nature. Primary lesions are defined as those that represent the initial pathologic change; secondary lesions result from external forces such as scratching, picking, or infection of primary lesions. An experienced dermatologist can often make the diagnosis from this descriptive information before even seeing the patient.

Morphology of Lesions

The morphology of individual lesions can be described in the following ways (Table 444-1): (1) whether they are flat, raised above the surface of the skin, or depressed; (2) the range of their size; (3) whether they are solid or contain fluid; and (4) how their color compares with the patient's normal skin. Morphologic terms have been developed to assess alterations in the stratum corneum and dermal or subcutaneous tissue. For example, the stratum corneum in psoriatic plaques can be silvery in color with densely adherent layers so that it looks like the mineral mica; this pattern is called a *micaceous scale*. Another usual morphologic feature is whether the individual lesions are monomorphic or polymorphic: all monomorphic lesions are the same shape, size, color, and consistency. Certain diseases, such as eruptive xanthoma, almost always have monomorphic papules, whereas other diseases, such as acne, are more likely to have polymorphic lesions that may represent either changes over time or a basic variability.

TABLE 444-1 TERMINOLOGY TO DESCRIBE THE MORPHOLOGY OF INDIVIDUAL SKIN LESIONS

TERM	DEFINITION	EXAMPLE
PRIMARY SKIN LESIONS: INITIAL PATHOLOGIC CHANGE		
Macule	Circumscribed change in skin color that is flush with the surrounding skin. Lesion is <1 cm in diameter.	Solar lentigo Traumatic purpura
Patch	Circumscribed change in skin color that is flush with the surrounding skin. Lesion is ≥1 cm in diameter	Cafe au lait spot Vitiligo
Papule	A solid or cystic elevation <1 cm in diameter	Acne Eruptive xanthoma
Nodule	A solid or cystic elevation >1 cm but <2 cm in diameter	Dermatofibroma
Tumor	A solid or cystic elevation >2 cm in diameter	Follicular cyst
Plaque	An elevated lesion that is >1 cm in diameter	Psoriasis
Scale	Desiccated, thin plates of cornified epidermal cells that form flakes on the skin surface	Ichthyosis
Wheal	Circumscribed, flat-topped, firm elevation of skin with a well-demarcated and palpable margin	Urticaria
Vesicle	Circumscribed, elevated lesion containing clear serous or hemorrhagic fluid that is <1 cm in diameter	Contact dermatitis Herpes simplex
Bulla	Circumscribed, elevated lesion containing clear serous or hemorrhagic fluid that is >2 cm in diameter	Bullous pemphigoid
Pustule	A vesicle containing purulent exudate	Folliculitis
Atrophy	A depression from the surface of the skin with underlying loss of epidermal or dermal substance	Lichen sclerosis et atrophicus
Erosion	A depression from the surface of the skin with a loss of all or part of the epidermis Can be a secondary lesion	Burn Ruptured bulla
Ulceration	A depression from the surface of the skin with a loss of the entire epidermis and at least some of the dermis Can be a secondary lesion	Ecthyma Excoriation of acne papule
SECONDARY SKIN LESIONS: RESULT FROM EXTERNAL FORCES SUCH AS SCRATCHING, PICKING, INFECTION, OR HEALING OF PRIMARY LESIONS		
Lichenification	Dry, leathery thickening of the skin with exaggerated skin markings	Chronic eczema
Scar	An elevated or depressed area of fibrosis of the dermis or subcutaneous tissue resulting from an antecedent destructive process	Healing wound
Fissure	A deep linear split in the skin extending through the epidermis	Traumatized eczema
Crust	Dried exudates of serum, blood, sebum, or purulent material on the surface of the skin	Acute and/or secondarily infected eczema

Distribution of Lesions

Many skin diseases commonly affect particular parts of the body surface (Table 444-2). In certain cases, the pattern of distribution is consistent with our understanding of the pathogenesis of a disease. For example, acne lesions are found on the parts of the skin that contain the highest concentration of

sebaceous glands, which are known to be involved in the development of acne. Other skin diseases are precipitated or caused by sun exposure, and their lesions are present only in sun-exposed areas of the body (e.g., lupus erythematosus or phototoxic drug eruptions). Dermatologic disorders that are the direct result of the patient's manipulation of the skin are found only where the patient can reach (e.g., the posterior shoulders but not the middle of the back).

The pattern of distribution, although poorly understood from a pathogenetic perspective, is extremely helpful for diagnosis (Fig. 444-1). For example, psoriasis often symmetrically affects the scalp, extensor arms and legs (elbows, knees, and shins), umbilicus, intragluteal cleft, and fingernails (Fig. 444-2; Chapter 446). Psoriatic lesions can involve the entire body surface, but an awareness of their common distribution guides the physical examination and aids accurate diagnosis. Conversely, atopic dermatitis (Chapter 446) typically involves the flexural arms and legs (antecubital fossae and popliteal fossae), wrists, nipples, and eyelids.

It is important to examine the mucous membranes of the mouth and the genital areas. Lichen planus (Chapter 446), a papulosquamous skin disease, often involves the volar wrists, shins, buccal mucosa, and shaft of the penis. In lichen planus, the oral and genital lesions may be asymptomatic, and the medical history cannot substitute for a careful physical examination.

TABLE 444-2 PREFERENTIAL DISTRIBUTION OF SELECTED SKIN DISEASES

DISTRIBUTION ON THE SKIN	SKIN DISEASE
Skin chronically exposed to sunlight (face, neck, hands, arms)	Actinic keratosis, basal cell carcinoma, squamous cell carcinoma
Central chest, shoulders, and earlobes	Keloids
Extensor arms and legs, intragluteal cleft, umbilicus	Psoriasis
Antecubital fossa, popliteal fossa	Atopic dermatitis
Anterior surface of lower legs	Palpable purpura, pretibial myxedema, necrobiosis lipoidica diabeticorum, erythema nodosum
Axilla and inguinal areas	Hidradenitis suppurativa
Posterior neck and back	Folliculitis
Web spaces of toes and sides of feet	Tinea pedis
Web spaces of fingers and wrists	Scabies
Palms and soles	Secondary syphilis, erythema multiforme

Arrangement of Lesions

The arrangement of several lesions in relation to each other can provide valuable diagnostic information. Terms that are commonly used to describe the relationship of lesions to each other include *clustered, grouped, linear, zosteriform, annular,* and *coalescing* (Table 444-3). *Clustered* lesions are arranged within a few millimeters of each other. When vesicular lesions are clustered on an erythematous base, the word *herpetiform* is used to describe their arrangement because this is the classic appearance of herpes simplex (Fig. 444-3; Chapters 382 and 447). *Grouped* lesions are arranged in the same body site, such as over a shoulder or elbow. A *linear* arrangement of lesions looks like a geometric line over any part of the body surface. One type of linear arrangement is called *koebnerization* (or the Koebner phenomenon), which occurs in particular skin diseases, such as psoriasis, in which new lesions evolve after traumatic injury. Linear lesions are frequently seen in allergic contact dermatitis if the offending antigen brushed against the skin to create a linear pattern of dermatitis. This pattern often results when a plant such as poison oak brushes against the skin (Fig. 444-4). A *zosteriform* arrangement refers to usually unilateral lesions in the cutaneous distribution of a spinal nerve dermatome; herpes zoster (Chapters 383 and 447) is the classic zosteriform dermatosis, but other lesions can arise in this arrangement. *Annular* lesions, which are round to oval with an area of central clearing, often consist

FIGURE 444-2. The distribution of psoriatic lesions is often symmetrical over the extensor surfaces of the skin.

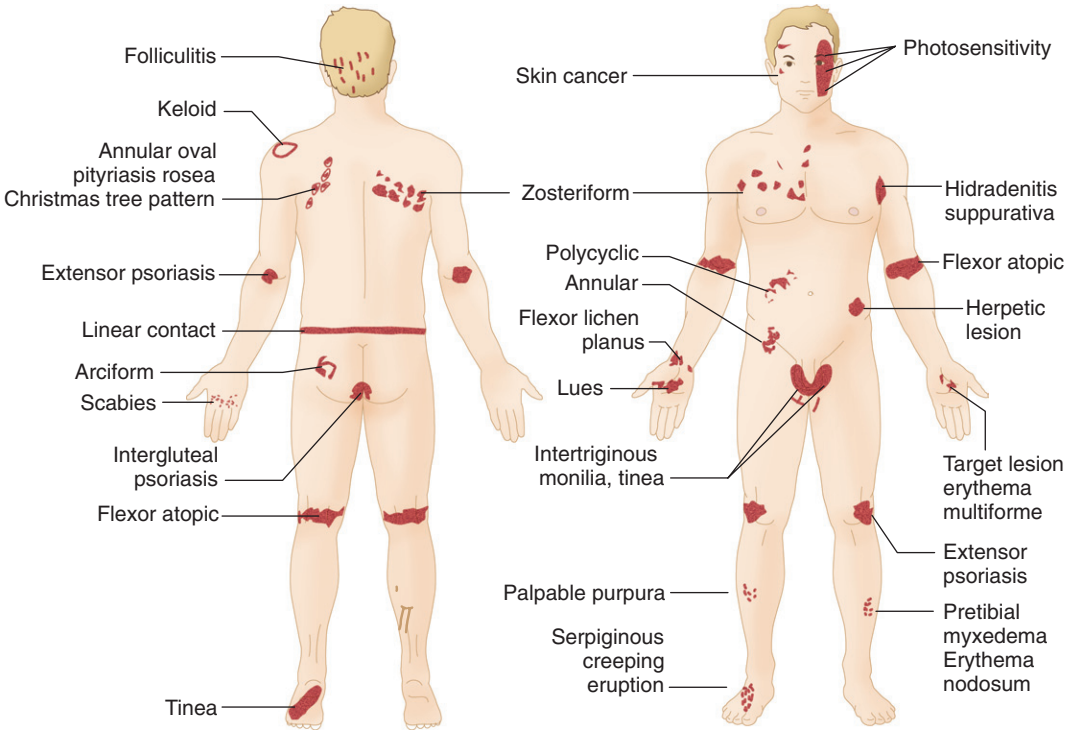

FIGURE 444-1. Configurational and regional diagnostic aids for the diagnosis of primary and secondary skin lesions.

TABLE 444-3 ARRANGEMENT OF SKIN LESIONS

TYPE OF ARRANGEMENT	EXAMPLE OF SKIN DISEASE
Clustered	Herpes simplex
Grouped	Lichen planus Granuloma annulare Dermatitis herpetiformis
Linear	Allergic contact dermatitis Epidermal nevus Morphea Koebnerized psoriasis
Zosteriform	Herpes zoster Metastatic breast carcinoma Hemangiomas of Sturge-Weber syndrome
Annular without scale	Secondary syphilis Lupus erythematosus Urticaria Hansen's disease (leprosy)
Annular with scale	Dermatophytosis Pityriasis rosea Erythema annulare centrifugum
Coalescing	Psoriasis Drug hypersensitivity eruption Viral exanthema Urticaria

FIGURE 444-3. This arrangement of vesicular lesions clustered on an erythematous base, seen here in a patient with herpes simplex, is termed *herpetiform*.

FIGURE 444-4. Allergic contact dermatitis occurring in a linear arrangement when the offending antigen, such as poison oak, is brushed against the skin in this way.

of an arrangement of smaller lesions in this configuration. Finally, almost all types of lesions can coalesce, meaning that individual lesions merge into each other. *Coalescing* lesions often assume annular or figurate patterns on the skin (Chapter 446).

Number of Lesions

At the most extreme, an eruption can cover nearly 100% of the skin surface. At the other end of the spectrum, only one or two lesions may be present. Certain diseases are characterized by an overall typical number of lesions on the skin. For example, patients with tuberculoid leprosy generally have fewer than five lesions on the entire skin surface. Other diseases, such as granuloma annulare, can range from a few lesions to hundreds of lesions. Sometimes the number of lesions is an indication of the severity of the disorder, as in widespread psoriasis. A general estimation of the number of lesions such as "more than 50 flat-topped papules distributed on the shins and wrists bilaterally" or "8 to 10 orange papules on each elbow" can also assist in guiding the physician to the correct diagnosis.

TABLE 444-4 MORPHOLOGY-BASED CLASSIFICATION OF MAJOR SKIN DISORDERS

GROUP	CLINICAL MORPHOLOGY	EXAMPLES OF DISEASES IN THE GROUP
Eczematous dermatitis	Erythematous macules, papules, vesicles, lichenification, fine scaling, excoriations, crusting	Contact dermatitis, atopic dermatitis, stasis dermatitis, photodermatitis, exfoliative dermatitis
Maculopapular eruptions	Macules, erythema, papules	Viral exanthems, drug hypersensitivity reactions, Kawasaki disease, vasculitic, purpuric eruptions
Papulosquamous dermatoses	Papules, plaques, and erythema with scales	Psoriasis, reactive arthritis, pityriasis rosea, lichen planus, seborrheic dermatitis, ichthyosis, secondary syphilis, mycosis fungoides
Vesiculobullous diseases	Vesicles, bullae, erythema	Herpes simplex and zoster, hand-foot-and-mouth disease, insect bites, bullous impetigo, scalded skin syndrome, pemphigus, bullous pemphigoid, dermatitis herpetiformis, porphyria cutanea tarda, erythema multiforme
Pustular diseases	Pustules, cysts, erythema	Acne vulgaris rosacea, pustular psoriasis, folliculitis
Urticaria and cellulitis	Wheals and figured, raised erythema, scaling	Urticaria, erythema annulare centrifugum, and erysipelas
Nodular lesions	Nodules and tumors, some associated with erosions and ulceration	Benign and malignant tumors—basal cell cancer, squamous cell cancer, rheumatoid nodules, xanthomas
Telangiectasia, atrophic, scarring, ulcerative diseases	Atrophic, sclerotic telangiectasia, ulcerative changes	Connective tissue diseases, radiation dermatitis, lichen sclerosus et atrophicus, vascular insufficiency (arterial and venous), pyoderma gangrenosum
Hypermelanosis and hypomelanosis	Increased and decreased melanin deposition in skin	Acanthosis nigricans, cafe au lait spots, vitiligo, tuberous sclerosis, xeroderma pigmentosum, melasma, freckles

Major Classifications

After carefully identifying the clinical features of skin lesions or eruptions, the physician can use the recognized patterns to classify the disease into a general category of skin disorders. The ability to identify the clinical features of a lesion's morphology allows cutaneous disorders to be placed in categories that narrow the differential diagnosis to a reasonable number of choices, which can then be further refined by considering the distribution, arrangement, and number of lesions (Table 444-4).

Eczematous dermatitis (Chapter 446) is a common superficial skin inflammation that is characterized by erythematous macules and papules in the early and mild stages. These changes can progress to vesiculation, oozing, fine scaling, and crusting. Because eczematous dermatitis is associated with pruritus (itching), the patient often excoriates the involved skin. In the chronic setting, lichenification caused by repeated rubbing is a typical secondary

FIGURE 444-5. Allergic contact dermatitis on the arm at the site of application of a topical antibacterial ointment to treat a burn wound. This cutaneous allergic response manifests as erythematous macules, papules, and vesicles where the allergen comes in contact with the skin.

FIGURE 444-7. Psoriasis is characterized by erythematous, scaling papules and plaques.

FIGURE 444-6. Palpable purpura (nonblanching red macules and papules) on the lower legs is typical of many types of cutaneous vasculitis.

FIGURE 444-8. Arthropod bite reactions on the skin of the back appear as multiple papulovesicles with surrounding erythema from assault by sand fleas while the patient was sleeping on the beach.

FIGURE 444-9. Monomorphous follicularly oriented pustules on the chest are seen in folliculitis.

clinical feature of eczematous dermatitis. The localized distribution of an eczematous eruption at the site of allergen exposure helps distinguish allergic contact dermatitis (Fig. 444-5) from other types of eczematous dermatoses, such as atopic dermatitis and stasis dermatitis, that tend to be bilaterally symmetrical and involve particular areas of the skin.

Maculopapular eruptions (Chapter 447) are characterized by erythema, macules, and papules. Many of these cutaneous eruptions, such as viral exanthems and drug eruptions, are often symmetrical, bilateral, and widespread. Cutaneous vasculitis shows clinical features of erythematous macules and papules that are commonly most prominent on the lower legs or other dependent portions of the skin. When the red macules and papules in vasculitic processes do not blanch with pressure, they are termed *palpable purpura* (Fig. 444-6).

Papulosquamous lesions (Chapter 446) are defined as papules with scaling. Psoriasis is a chronic proliferative epidermal disease that typifies the papulosquamous skin disorders. This inflammatory disease, which may have a genetic component, often begins with red macules that progress to scaly papules and plaques (Fig. 444-7). Psoriatic plaques have a propensity to develop on the elbows, knees, and scalp but can involve any part of the skin. If the psoriatic process becomes widespread, the entire skin surface can be involved, and the syndrome is then termed *erythroderma*.

In vesiculobullous diseases (Chapter 447), cleavage at particular levels in the epidermis or dermis results in the clinical appearance of vesicles or bullae, often with surrounding erythema. This broad morphologic group comprises genetic and acquired diseases with a variety of etiologies. For example, insect (arthropod) bite reactions are a common cause of vesiculobullous lesions with surrounding erythema, distributed in patterns that relate to the site of interaction with the particular offending insect (Fig. 444-8).

The hallmark of pustular skin diseases (Chapter 447) is the presence of small, circumscribed, elevated lesions containing purulent exudates, often with associated erythema. Cystic lesions are pustular lesions larger than 1 cm. Pustules may be sterile, as in pustular psoriasis, or may contain microbial organisms, as in acne (Chapter 447). Folliculitis is a pustular skin infection located within hair follicles and often surrounded by erythema (Fig. 444-9).

Skin disorders arising as urticaria (Chapter 448) or cellulitis (Chapter 449) share clinical features of wheals, figured raised erythema, and occasionally scaling. Urticaria is an inflammatory mast cell–mediated process that may have an allergic or nonallergic cause and is characterized by clinical lesions called wheals, which are evanescent, erythematous, rounded or flat-topped, elevated (edematous) lesions (Fig. 444-10). Although the borders of a wheal are sharply demarcated, they tend to be transient and may appear and disappear in a matter of hours. Wheals may be round, oval, serpiginous, or annular in appearance and can range in size from several millimeters to more than 10 cm. Itching is often intense in the affected skin but resolves as the wheal

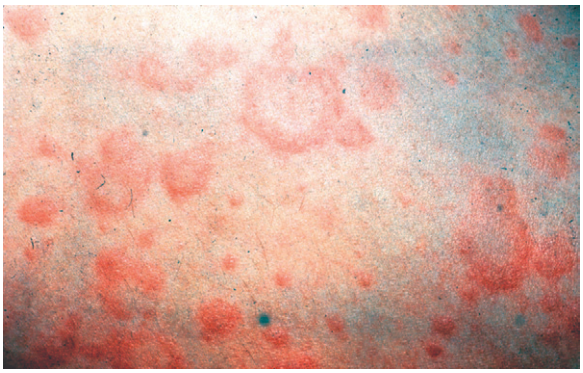

FIGURE 444-10. This eruption consisting of evanescent, annular wheals is termed *urticaria*.

FIGURE 444-11. This nodule represents a neglected basal cell carcinoma. The lesion is well defined and sharply demarcated from normal skin. The rolled smooth border with telangiectasias surrounds several crusted ulcerations.

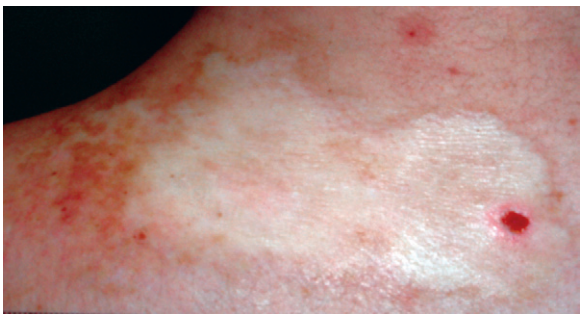

FIGURE 444-12. This single plaque of morphea manifests as localized induration of the skin with central atrophy and hypopigmentation with a peripheral rim of erythema.

FIGURE 444-13. Widespread hypopigmented and hyperpigmented macules on sun-exposed skin are a clinical feature of xeroderma pigmentosum after exposure to normal amounts of sunlight over time.

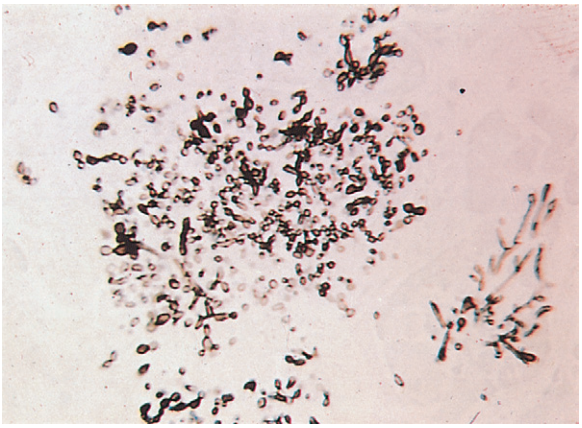

FIGURE 444-14. ***Candida albicans*.** Potassium hydroxide examination of candidal skin lesion shows short, stubby hyphae and budding yeast elements.

fades. In contrast to urticaria, the erythematous, raised lesions seen in cellulitis have an infectious cause and tend to expand in a centrifugal pattern until appropriate antibiotic treatment is initiated.

Nodular lesions (Chapter 448) may be single or multiple nodules and may have associated erosions or ulcerations. Basal cell carcinoma (Chapter 210), a common malignant tumor of the skin, is linked to decades of cutaneous sun exposure (Fig. 444-11). In addition, a large variety of inflammatory and infectious diseases of the skin are associated with nodular lesions.

Skin diseases sharing the morphologic features of telangiectasia, atrophy, scarring, and ulceration can be classified together, although there is a wide range of causes, including connective tissue diseases, such as localized or systemic scleroderma. A localized type of cutaneous scleroderma, termed *morphea* (Chapter 275), is characterized by single or multiple discrete patches or plaques of indurated skin, often accompanied by cutaneous atrophy and pigmentary changes (Fig. 444-12).

Hypermelanosis and hypomelanosis (Chapter 449) occur in a wide range of cutaneous disorders in which there is increased or decreased melanin deposition in the skin. These skin lesions may appear dark (hyperpigmented), as seen with cafe au lait spots, or pale (hypopigmented), as seen with vitiligo. Xeroderma pigmentosum is a rare, genetic disease in which patients cannot repair DNA damage induced by ultraviolet irradiation and develop early freckling that progresses to widespread hypopigmented and hyperpigmented macules over time (Fig. 444-13). Most important, without meticulous protection from ultraviolet irradiation of the skin, these patients suffer from cutaneous neoplasms, including malignant melanoma (Chapter 210), in the early decades of life.

Diagnostic Tests

After a reasonable differential diagnosis has been created, diagnostic tests can narrow the differential or confirm the correct diagnosis. Several diagnostic tests can be performed in the physician's office after collecting material from the surface of the skin. The potassium hydroxide preparation of scale and pustules is used to look for microscopic hyphae or pseudohyphae that indicate the presence of a dermatophyte infection or yeast infection (Fig. 444-14; Chapter 446). The Gram stain of pustules or bullae is used to determine whether bacteria are present or whether the lesion is sterile (Chapter 447). The Tzanck preparation of the base of a vesicle is used to look for rounded, multinucleated keratinocytes that indicate a herpesvirus infection (Fig. 444-15; Chapter 447). The oil mount of skin scrapings from the base of a burrow or pruritic papule is used to look for the mites or eggs that indicate a scabies infestation (Fig. 444-16; Chapter 367). When an infection is suspected, it is often necessary to obtain specimens for culture by swabbing

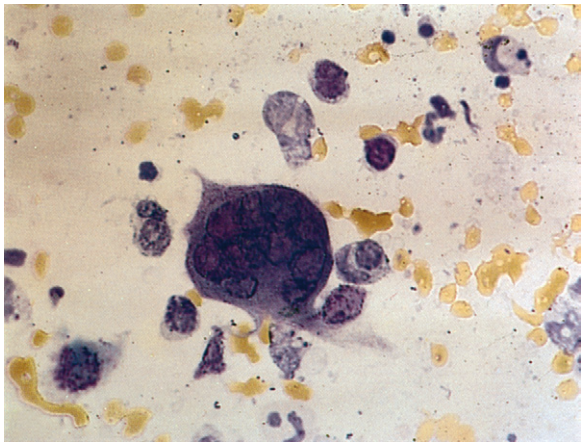

FIGURE 444-15. Tzanck smear of herpes simplex. Positive Tzanck smear is seen as multinucleated giant cell.

FIGURE 444-16. A scabies mite is seen on this microscopic examination of an oil mount of a scraping taken from the end of a small burrow on the wrist.

pustules, bullae, or abscesses. Any overlying crust should be removed before obtaining the culture specimen. Scale from the surface of the skin can also be sent for fungal culture to increase the detection of dermatophyte infections, especially those involving the nails.

Skin Biopsy

Skin biopsies are performed to aid in the diagnosis of cutaneous infections and in the histologic diagnosis of inflammatory and neoplastic skin disorders. If bacterial cellulitis is suspected, tissue from the dermis can be obtained by performing a punch biopsy of the affected skin and submitting the core of tissue for bacterial culture. To diagnose deep fungal or mycobacterial infections, tissue usually must be obtained by this type of biopsy and sent for culture under appropriate temperature conditions.

Skin biopsies of cutaneous growths or inflammatory eruptions are an essential tool when the diagnosis is not certain (Fig. 444-17). The term *biopsy* may also be applied to the surgical removal of benign skin lesions such as warts and skin tags. Many dermatologists follow the general practice of sending all excised skin tissue for histologic assessment.

Biopsy of Possible Malignancy

Any lesions that have features of basal cell carcinoma or squamous cell carcinoma should undergo biopsy (Chapters 210 and 448). Clinical indications for biopsy of lesions suspected to be malignant include lesions that fail to heal, increase in size, bleed easily, or ulcerate spontaneously. Actinic keratoses, which are considered to be precancerous lesions, are usually treated without preceding biopsy. The usual biopsy approach to nonmelanotic lesions that protrude from the surface of the skin is to perform either a snip biopsy (with scissors) or a shave biopsy (with a blade). If the entire lesion is removed, it can be considered an excisional biopsy.

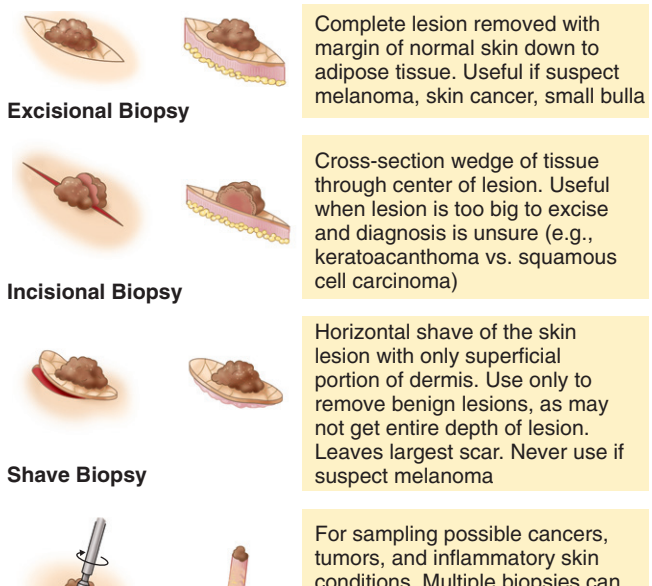

FIGURE 444-17. Methods of skin biopsy.

Punch Biopsy

For inflammatory skin lesions, it is usually necessary to obtain tissue down to subcutaneous fat for an accurate assessment of the inflammatory process. A punch biopsy using an instrument 3 to 8 mm in diameter to "core out" a piece of skin tissue is the preferred approach. If multiple lesions are present, it is prudent to select a lesion that is not in a cosmetically important area because a scar will occur at the punch biopsy site but to be sure to select a representative lesion that has not been altered by scratching, infection, or lichenification. The punch biopsy wound heals best when closed with one to two sutures, but it can be left to heal by granulation. Some inflammatory skin disorders, especially bullous disorders, have characteristic autoantibody deposition that can be assessed by direct immunofluorescence of biopsy tissue. This test is performed in specialized dermatopathology laboratories.

The approach to biopsy of lesions that have clinical features of malignant melanoma is critical. First, there is only one opportunity to obtain tissue correctly to maximize the chance of accurate diagnosis. Second, an improperly obtained biopsy specimen can make it impossible to assess the patient's risk for metastatic disease. When malignant melanoma is suspected, the lesion should be removed entirely with an elliptical excisional biopsy; margins of normal skin are not included in the excised tissue. A shave biopsy should be avoided because it does not allow the full depth of the lesions to be determined histologically. The thickness of the lesion remains the most accurate way to predict metastatic disease and is critical for planning adjuvant therapy (Chapters 210 and 448). A punch biopsy should be avoided because it does not provide the dermatopathologist with the full histologic architecture of the lesion. When clinical features of a pigmented lesion of the skin are highly suggestive of malignant melanoma, the patient should usually be referred to a dermatologist before performing the biopsy to ensure that the most accurate histologic information is obtained to guide clinical treatment.

445 PRINCIPLES OF THERAPY OF SKIN DISEASES

VICTORIA P. WERTH

The goal of therapy is to improve a skin condition with the least toxic and most specific approach. Because many treatments or medications can be applied directly to the skin, the option for topical therapy is attractive for treating many dermatologic diseases. However, many diseases require systemic therapy, particularly when patients have widespread involvement of the skin or a disease that cannot be improved with topical therapy. Therapies work by improving barrier function, removing scale, altering inflammation in the skin, altering blood flow, providing antimicrobial effects, or affecting proliferating cells. Recent advances in the understanding of cutaneous biology have not been routinely accompanied by evidence-based documentation of the benefits of many specific therapies.

PRINCIPLES OF TOPICAL THERAPY

Soaks and Dressings

Water or saline applied by soaks and wet dressings can be beneficial for many skin conditions, including ulcers, by promoting healing of the epidermis and débridement of crusts. Soaked gauze is applied to involved areas for 15 to 30 minutes several times a day, and care should be taken not to allow the gauze to dry and adhere. If adherence occurs, the gauze should be soaked before the dressing is removed. Use of strong antiseptic solutions, including hydrogen peroxide, is not recommended because of toxicity to cells. Whirlpool action can enhance débridement. When large areas of skin are involved, baths are a convenient way to treat the skin with medications that reduce itching and inflammation. The best time to apply moisturizers that help trap water in the upper layers of skin is immediately after a bath or shower.

Wet-to-dry dressings are rarely used, except when initial vigorous wound débridement is necessary. Continued use after wounds are débrided traumatizes wounds and delays healing. Moist wound healing, which is often ideal, can be accomplished with a topical antibiotic such as a combination of polymyxin B and bacitracin (Polysporin) or mupirocin (Bactroban), gauze impregnated with petrolatum (Vaseline), or an occlusive hydrocolloid dressing. Little evidence indicates that débriding enzymes are beneficial. Compression with an Unna or multilayered boot, which includes an elastic dressing such as Coban, can decrease local edema and facilitate wound healing. Polysporin/petrolatum gauze or occlusive dressings are placed underneath, an approach that is helpful for chronic venous, diabetic, and pressure ulcers, as well as for acute wounds. Closed wet dressings, in which gauze is soaked and then covered with an impervious material, can help when maceration and heat retention are needed. Biologic dressings with skin substitutes or keratinocytes can be beneficial for wounds that are resistant to healing. Skin grafts can also facilitate healing of otherwise nonhealing wounds. Platelet-derived growth factor, which is approved for use on diabetic ulcers, can modestly improve wound healing.

Topical Medications

Topical medications mix an active drug with preservatives, emulsifying agents, and an appropriate base or vehicle. Systemic absorption varies among patients, sites, and vehicles. Topically applied drugs are absorbed more readily through inflamed, thin skin. The base can be any of the following: a *powder*, which promotes dryness and is used to reduce maceration in intertriginous areas; a *lotion*, which is a suspension of oil in water; *solutions*, which include water, alcohol, and propylene glycol, but not oil; *gels*, which are solid at room temperature but melt on contact with the skin; a *cream*, which is an emulsion of oil in water that leaves a thin oil coating as the water evaporates; an *ointment*, which combines oils, such as petrolatum (Vaseline), with small amounts of water and which is more occlusive and hence increases the absorption of medication but also results in a greasier appearance; a *paste*, which is a mixture of powder and ointment; or a *spray*. Lotions, solutions, and gels provide less penetration than ointments do, but they are especially useful for the treatment of hair-bearing areas such as the scalp, where greasiness is displeasing. Creams are less greasy than ointments and are useful for the face, groin, and intertriginous areas. Ointments are often more effective for dry, scaly conditions such as eczema and psoriasis and are helpful in areas that have thick skin, such as the palms and soles, but they should be avoided in infected or intertriginous areas. The choice of base is determined by the skin condition and location. Impregnated tapes are another delivery method to provide occlusion and protect the skin from manipulation.

ANTI-INFLAMMATORY AGENTS

Glucocorticoids

Topical glucocorticoids work because of their effects on vasoconstriction, proliferation, immunosuppression, and inflammation. Assays related to the ability to vasoconstrict and clinical trials of efficacy have allowed glucocorticoids to be divided into various classes based on potency (Table 445-1). These medications are typically used twice a day. Side effects include atrophy of the skin, telangiectases, purpura, striae, local skin infections (e.g., folliculitis, tinea, and candidiasis), hypopigmentation, hypertrichosis, systemic adrenal suppression when these agents are used on as little as 20% of the skin's surface area, and glaucoma when they are used around the eye. Side effects are especially prevalent when fluorinated steroids are used on thin skin (e.g., face, groin, or scrotum), and prolonged use on the face can result in facial dermatitis, acne, and an eruption resembling acne rosacea that is often exacerbated when use of the steroid is terminated. Certain conditions are more responsive to steroids, and the potency of the steroid chosen must be based on the condition and its location (Table 445-2). The superpotent class I agents should be restricted to patients with severe dermatoses, and their use should normally not exceed 2 weeks. Patients who receive these potent agents require frequent follow-up and must be carefully evaluated for the need to continue strong topical steroids. Use of any fluorinated steroid on the face requires an exact diagnosis and should be limited in the extent of application and duration of use. Intralesional glucocorticoids can be injected into individual lesions to improve delivery of the medication, and this method is commonly used to treat patients with acne cysts, hypertrophic scars, keloids, alopecia areata, granuloma annulare, discoid and panniculitic lupus erythematosus (Chapter 274), psoriasis, and lichen simplex chronicus. Triamcinolone acetonide is most frequently used, followed by the longer-acting triamcinolone hexacetonide. It is important to use proper dilutions, such as 2.5 mg/mL on the face and 5 mg/mL elsewhere, to avoid local skin atrophy.

Systemic glucocorticoids are used for acute and chronic conditions in dermatology, but they should be avoided, if possible, or minimized because of their well-known side effects (Chapter 34). Acute conditions that commonly require systemic steroids include severe contact dermatitis such as poison ivy, photodermatitis, severe atopic dermatitis, and acute urticaria. Many skin conditions such as psoriasis and eczema become exacerbated when use of the steroids is tapered, so steroids should be avoided when possible in these conditions. The dose of steroid must be individualized to the condition and its severity. Steroid-sparing drugs, such as immunosuppressive agents, can be used to minimize the long-term use of steroids for selected conditions.

TABLE 445-1 RANKING OF SOME COMMONLY USED TOPICAL STEROIDS BY POTENCY

Super potency	Clobetasol propionate (Temovate ointment and cream), betamethasone dipropionate (Diprolene cream and ointment), diflorasone diacetate (Psorcon E ointment), halobetasol propionate (Ultravate ointment)
High potency	Amcinonide, mometasone furoate ointment, diflorasone diacetate (Florone ointment), halcinonide 0.1% cream, fluocinonide, desoximetasone, triamcinolone acetonide, diflorasone diacetate ointment and cream, betamethasone dipropionate (Diprosone), betamethasone benzoate and valerate
Medium potency	Fluticasone propionate; mometasone furoate cream; halcinonide 0.25% ointment; triamcinolone acetonide 0.1% cream and lotion; fluocinolone acetonide 0.2%, 0.25%, and 0.1% cream and 0.25% ointment and 0.5% solution; hydrocortisone valerate 0.2% ointment and cream; alclometasone dipropionate 0.5% ointment; betamethasone dipropionate 0.5% lotion; hydrocortisone butyrate 0.1% cream; betamethasone benzoate 0.25% cream; betamethasone valerate 0.1% cream and 0.5% lotion; flumethasone pivalate 0.3% cream; desonide 0.5% cream
Low potency	Hydrocortisone 1% cream

TABLE 445-2 CLINICAL APPLICATION OF TOPICAL GLUCOCORTICOIDS

Super potency and high potency	Plaque and palmoplantar psoriasis, lichen planus, dyshidrotic eczema, lichen simplex chronicus, granuloma annulare, sarcoidosis
Medium potency	Dermatitis: allergic contact, atopic, neurodermatitis
Low potency	Intertrigo, pruritus ani, seborrheic dermatitis

Nonsteroidal Anti-inflammatory Agents

Psoriasis Therapies

Tars and anthralin are used for psoriasis (Chapter 446). Tars are most commonly used in conjunction with ultraviolet B (UVB) light. Tars are also used in shampoos and bath oils to treat seborrhea and psoriasis. Anthralin is a synthetic hydroxyanthrone that inhibits keratinocyte proliferation; it stains and can be irritating, but it can be effective therapy (Chapter 446).

Calcipotriol

Calcipotriol is a vitamin D derivative that has antiproliferative and immunomodulatory effects on skin. Hypercalcemia can occur if more than 100 g/wk is used, so this agent cannot be used for widespread disease. It is applied twice daily, can be irritating on thin skin, and takes 6 to 8 weeks to be effective.

Retinoids

The retinoids are a group of compounds that include vitamin A and its derivatives. Their effects are mediated through several different classes of receptors, and the receptor-drug complex has effects on other regulatory proteins that affect growth factors, oncogenes, keratins, or transglutaminases. Retinoids affect cell growth, differentiation, and morphogenesis; inhibit tumor promotion and malignant cell growth; have immunomodulatory effects; and alter cell cohesion.

Topical retinoids include all-*trans*-retinoic acid (tretinoin), which is approved for acne (Retin-A) and photoaging (Renova 0.05% cream) and is also useful for hyperpigmentation, steroid-induced atrophy, and early stretch marks. Tretinoin is available as a cream (0.025%, 0.05%, 0.1%), a gel (0.01%, 0.025%), and a solution (0.05%). Adapalene (Differin 0.1% gel) and tazarotene (Tazorac) are used for acne (Chapter 447). Tazarotene is also used for psoriasis, often in combination with topical steroids to minimize irritation. Bexarotene (Targretin) 1% gel is used for the topical treatment of cutaneous lesions in patients who have refractory or persistent stage IA or IB cutaneous T-cell lymphoma. Topical retinoids can be irritating and frequently cause an exacerbation before improvement. However, they should be used regularly on lesion-prone skin to produce improvement. Moisturizers may be needed to minimize drying effects.

Systemic retinoids commonly used for the skin include isotretinoin, acitretin, and bexarotene (Targretin). They have many applications, but most frequently isotretinoin (Accutane) is used for cystic and conglobate acne, acitretin for severe psoriasis (especially the erythrodermic and pustular forms), and bexarotene for cutaneous T-cell lymphoma. Isotretinoin and acitretin have also been used to treat several forms of ichthyosis and lupus erythematosus and for the chemoprevention of skin cancers, particularly in immunosuppressed transplant recipients. The many side effects of systemic retinoids include teratogenicity, cheilitis, hair loss, headaches, hyperlipidemia, abnormal liver enzyme levels, vertebral hyperostosis, tendon and ligament calcification, osteoporosis, and central hypothyroidism with bexarotene. Pregnancy must be avoided, and the use of retinoids in women of childbearing age therefore requires careful monitoring. Treatment of acne is reserved for cases of cystic acne not responding to less toxic therapies; in this setting, a 4- to 5-month course of Accutane, 0.5 to 1 mg/kg/day, is curative in 85 to 90% of patients.

Antimalarial Drugs

Aminoquinolines include chloroquine, hydroxychloroquine, and quinacrine. These agents have inhibitory effects on pro-inflammatory cytokine production, DNA replication, and chemotaxis. They are useful in patients with connective tissue diseases, polymorphous light eruption, sarcoidosis (Chapter 95), porphyria cutanea tarda (Chapter 447), sclerosing conditions, and vasculitis. Side effects include diarrhea, headache, irritability, psychosis, skin dyspigmentation, and rarely, retinopathy. Retinopathy is rare if doses of chloroquine are 3.5 mg/kg/day or less and doses of hydroxychloroquine are 6.5 mg/kg/day or less. Combinations of hydroxychloroquine or chloroquine with quinacrine are frequently helpful when a solitary agent is inadequate. The combination of hydroxychloroquine and chloroquine should not be used because of the additive risk for retinopathy.

Dapsone

Dapsone is a sulfone that inhibits the response of neutrophils and possibly eosinophils to chemotactic stimuli. It is useful for dermatitis herpetiformis (Chapter 447), cutaneous vasculitis (Chapter 448), pyoderma gangrenosum (Chapter 143), bullous lupus erythematosus (Chapter 274), Behçet's disease (Chapter 278), and autoimmune bullous diseases (Chapter 447). Side effects include hemolysis, methemoglobinemia, peripheral neuropathy, agranulocytosis, and rarely, a hypersensitivity syndrome with hepatitis, fevers, and rash. The glucose-6-dehydrogenase level should be checked before starting the drug, and it is common for patients with a normal glucose-6-dehydrogenase level to experience a 2-g/dL decrease in hemoglobin after achieving therapeutic doses of 100 to 200 mg/day.

Thalidomide

Thalidomide has potent anti-inflammatory effects, probably resulting from inhibition of tumor necrosis factor-α. It also modifies adhesion molecules on circulating leukocytes. Thalidomide is a serious teratogen, and patients must comply with strict birth control and monitoring. It is effective at a dose of 50 to 100 mg/day, with improvement beginning in 2 weeks and a full clinical response seen in 2 to 3 months in patients with severe cutaneous lupus erythematosus (Chapter 274), erythema nodosum leprosum (Chapter 446), aphthae, Behçet's disease (Chapter 278), actinic prurigo, chronic graft-versus-host disease (Chapter 181), multiple myeloma (Chapter 193), and numerous other inflammatory dermatoses. Besides teratogenesis, the main side effects include peripheral neuropathy, constipation, sedation, and rarely, amenorrhea.

Gold

Intramuscular gold has been used to treat pemphigus vulgaris (Chapter 447), with success as a solitary agent. A total dose of 400 to 600 mg of gold is often required to stop the formation of blisters; after the initial test doses, gold is administered at 50 mg once a week.

Colchicine

Colchicine, usually at a dose of 0.6 mg twice a day, is used for leukocytoclastic vasculitis (Chapter 447) and Behçet's disease. The main side effect of this low oral dose is diarrhea.

ANTIMICROBIAL AGENTS

Antibacterials

Topical antibiotics are used to treat superficial skin diseases, such as acne and folliculitis, that are associated with infectious organisms, as well as skin wounds and ulcers. They may work by decreasing neutrophil chemotaxis and other anti-inflammatory mechanisms. Topical solutions, gels, pledgets, and ointments are available, depending on the agent, and antibiotics include erythromycin, clindamycin, tetracycline, and metronidazole. Benzoyl peroxide also has antibacterial properties and is quite effective for mild to moderate acne (Chapter 447). Bacitracin and Polysporin ointments are typically used for wounds, but they can cause contact hypersensitivity; neomycin should be avoided because of the high incidence of allergic reactions. Mupirocin is particularly effective against *Staphylococcus* and *Streptococcus* species, and it can be used in the nose for carriers of staphylococci. Systemic antibiotics such as penicillins, cephalosporins, and erythromycin are used in patients with soft tissue infections such as impetigo, folliculitis, furuncles, carbuncles, cellulitis, ecthyma, erysipelas, postoperative wound infections, and necrotizing fasciitis. Tetracycline, doxycycline, and minocycline are used for acne, rosacea, and perioral dermatitis. Fluoroquinolones such as ciprofloxacin are useful for the treatment of gram-negative soft tissue infections.

Antifungals

Topical antifungal agents are used in patients with limited superficial fungal infections of the skin (Chapter 446). The numerous topical antifungal drugs available include the azoles (clotrimazole, econazole, ketoconazole, oxiconazole, and miconazole), which are available as creams and lotions applied

once or twice daily. The creams tend to be more effective. Topical agents used for dermatophytes, but not *Candida*, are haloprogin and tolnaftate. The newer allylamine antifungals naftifine and terbinafine have fungicidal effects. Ciclopirox 8% topical solution was recently approved for use in treating and preventing relapses of onychomycosis. Nystatin creams, oral suspensions, and vaginal tablets are effective for the treatment of *Candida* infections. The combination of antifungals with potent topical steroids such as betamethasone dipropionate is not advised because of increased side effects from the steroid and decreased efficacy of the antifungal as a result of the concomitant steroid.

Systemic antifungal agents include griseofulvin, terbinafine (allylamine), ketoconazole (imidazole), itraconazole, and fluconazole. These agents are used for extensive or severe superficial skin fungal infections (Chapter 446) caused by dermatophytes, *Candida*, or *Malassezia furfur* or for local infections not responsive to topical drugs, such as those found in the nails and scalp. Itraconazole and terbinafine are the only oral antifungals approved in the United States for the treatment of onychomycosis, and griseofulvin is the only oral agent approved for tinea capitis. Griseofulvin is best taken with a fatty meal to improve absorption and is the only antifungal drug not requiring regular monitoring of liver enzymes. Griseofulvin shows weak affinity for keratin, and thus it must be used for 18 months for onychomycosis of the toenails and 6 months for the fingernails to achieve even relatively poor cure rates. Terbinafine is the only fungicidal drug, whereas the rest are fungistatic. The number of interactions with medications is lower with terbinafine than with the triazole antifungals and ketoconazole because terbinafine does not inhibit or induce hepatic isoenzyme CYP3A4 (Chapter 28). However, terbinafine affects CYP2D6, another hepatic isoenzyme, so it is relatively contraindicated in patients who are taking cyclosporine or rifampin. Itraconazole and fluconazole have been used in pulse-dosing regimens for the treatment of onychomycosis. Fluconazole and terbinafine are not dependent on gastric acidity for optimal gastrointestinal absorption. Overall, the side effects of the systemic antifungal agents are similar and include headache and gastrointestinal symptoms (griseofulvin, terbinafine), nausea and vomiting (itraconazole, fluconazole, ketoconazole), hepatitis, and lupus-like syndromes (terbinafine).

Antivirals

Verrucae are treated with various destructive modalities, including 50 to 80% dichloroacetic acid and trichloroacetic acid solutions, podophyllin resin, and podofilox. Topical antiviral creams such as penciclovir and acyclovir do not significantly shorten the course of herpes simplex. Systemic antiviral drugs include acyclovir, valacyclovir, famciclovir, and foscarnet, which are used to treat primary and recurrent herpes simplex (Chapter 382) and herpes zoster (Chapter 383), although only acyclovir is approved for treatment of herpes zoster. These agents specifically block the function of herpesvirus DNA polymerase. Valacyclovir and famciclovir are available only orally in the United States, but their prolonged intracellular half-life allows less frequent dosing than with acyclovir. Patients with herpes zoster require higher doses than do patients with herpes simplex. Side effects include nausea and headaches. The varicella-zoster vaccine has significantly decreased the incidence of herpes zoster in individuals older than 60 years.■

Antiparasitics

Topical antiparasitic medications are used to treat pediculosis capitis, pediculosis pubis, and scabies. In addition, topical metronidazole has anti-inflammatory properties and is used to treat rosacea. For pediculosis and scabies, clothing and bedding must be washed, and all family members must be treated. Effective treatment includes 1% γ-benzene hexachloride (lindane), a chlorinated hydrocarbon pesticide that should not be used on young children or on pregnant or lactating women. It is ineffective against nits and thus must be reapplied after 1 week. Permethrin 5% cream (Elimite) for scabies or 1% cream rinse is particularly effective for head lice and requires just one application; 10% crotamiton (Eurax) and 5% topical sulfur ointments are less effective. Malathion is a moderately toxic organophosphate insecticide, but it must be applied overnight to treat lice. Pyrethrins (RID, Nix) are best used twice, one week apart, to treat head lice and nits.

ANTIPRURITIC OR ANESTHETIC AGENTS

Topical Analgesics

Capsaicin, an active ingredient of cayenne peppers and other plants of the genus *Capsicum*, is used for postherpetic neuralgia and other painful nerve-related conditions. It causes excitation of neural afferent C fibers and reduces substance P levels. Capsaicin causes a burning sensation and is applied four to five times daily for 5 to 6 weeks. Eutectic mixture of local anesthetic (EMLA) is a mixture of lidocaine and prilocaine that is used under occlusion to induce cutaneous anesthesia before a procedure. Lidocaine can be used as a topical anesthetic, but benzocaine should be avoided because it is a sensitizer.

TABLE 445-3 OVERVIEW OF ANTIHISTAMINES

ANTIHISTAMINE GROUP	GENERIC NAME	AVERAGE ORAL ADULT DOSES
FIRST-GENERATION H_1-TYPE ANTIHISTAMINES		
Alkylamine	Brompheniramine (Dimetapp)	4 mg q4-6h
	Chlorpheniramine (Chlor-Trimeton)	4 mg q4-6h (short acting); 8-12 mg q8-12h (long acting)
Amino alkyl ether (ethanolamine)	Clemastine fumarate	1.34 mg bid or 2.68 mg qd-tid
	Diphenhydramine (Benadryl)	25-50 mg q4-6h
Ethylenediamine	Pyrilamine (Triaminic)	30 mg bid
Phenothiazine	Promethazine (Phenergan)	10-12.5 mg qid
	Trimeprazine (Temaril)	2.5 mg q6h
Piperidine	Azatadine	1-2 mg q8-12h
	Cyproheptadine	4 mg q8h
	Diphenylpyraline	2 mg tid-qid
Piperazine	Hydroxyzine (Atarax)	25-100 mg tid-qid
SECOND-GENERATION H_1-TYPE ANTIHISTAMINES		
Alkylamine	Acrivastine (combined with pseudoephedrine in allergy medication)	8 mg qid
Piperidine	Astemizole (Hismanal)	10 mg qd
	Loratadine (Claritin)	10 mg qd
	Fexofenadine (Allegra)	60 mg bid or 180 mg qd
Piperazine	Cetirizine (Zyrtec)	5-10 mg/day
H_2-TYPE ANTIHISTAMINES		
	Cimetidine (Tagamet)	400 mg bid
	Ranitidine (Zantac)	150 mg bid
	Famotidine	10 mg bid
	Nizatidine	300 mg hs
H_1- AND H_2-TYPE ANTIHISTAMINES		
	Doxepin (Sinequan)	10-25 mg hs

bid = twice daily; hs = at bedtime; qd = once daily; qid = four times daily; tid = three times daily.

Antipruritic Agents

Doxepin 5% cream is used for localized pruritus. Menthol is a cyclic terpene plant alcohol used for non–histamine-related itching. Pramoxine hydrochloride is a topical anesthetic used for mild to moderate itching. Oral antihistamines play an important role in controlling pruritus in many skin conditions (Table 445-3), especially those mediated by histamine, such as urticaria, angioedema, and urticaria pigmentosa. The sedating and anticholinergic properties of many H_1-receptor antihistamines probably account for some of their efficacy. H_1-receptor antihistamines are the cornerstones of routine therapy, and if an agent from one group of H_1-receptor antihistamines is ineffective, an agent from a different class should be administered or combined. Second-generation H_1-receptor antihistamines are less sedating and are used if patients cannot tolerate or do not improve after taking first-generation agents. The combination of two different H_1-receptor antihistamines can be used when a solitary agent does not work; in particular, use of a sedating antihistamine at night and a second-generation antihistamine during the day can be helpful. The skin contains both H_1- and H_2-receptors, and occasionally combining H_1- and H_2-receptor antagonists can be beneficial. Usually, first-generation agents (e.g., hydroxyzine, 10 to 25 mg every 6 hours) are started at low doses and increased as tolerated, and regular continuous dosing is recommended. The tricyclic antidepressant doxepin, normally started at 10 to 25 mg at bedtime, has both anti–H_1- and H_2-receptor activity, but it interacts with drugs metabolized by the cytochrome P-450 pathway. Side effects

of commonly used first-generation antihistamines include sedation, dry mouth, blurred vision, constipation, and urinary retention, and lower doses may be required in elderly patients. The recommended dose for second-generation antihistamines (e.g., fexofenadine, 60 mg twice daily) should not be exceeded.

AGENTS THAT IMPROVE SURFACE FUNCTIONS (LUBRICATION, SCALE)

Moisturizers

Moisturizers improve skin by diminishing scale and increasing water content. They usually contain mixtures of water and fatty substances such as petrolatum, lanolin, lanolin derivatives, and fatty alcohols. Greasy moisturizers tend to function better, but they are less acceptable cosmetically.

Keratolytics

α-Hydroxy acids (lactic acid, glycolic acid, citric acid, glucuronic acid, pyruvic acid) are extremely effective keratolytics. They are helpful in treating disorders of keratinization and photoaging, as well as acne. Propylene glycol, used in 40 to 60% aqueous solutions, can decrease scaling. Salicylic acid, which works by decreasing keratinocyte adhesion and hydrating keratins, is used in a range of concentrations with many different bases to remove scale, to soften the stratum corneum, or as destructive therapy to remove warts and calluses. Urea is used in varying concentrations to treat scaling.

IMMUNE THERAPIES

Hormonal Therapies

Systemic therapies to modulate androgen production can be beneficial in patients with acne and hidradenitis suppurativa. Such treatments for moderate acne include spironolactone and, in women, Food and Drug Administration–approved combination oral contraceptives, e.g., Ortho Tri-Cyclen (norgestimate and ethinyl estradiol), Estrostep (norethindrone acetate and ethinyl estradiol), and Yaz (drospirenone and ethinyl estradiol), as they would be prescribed for contraception (Chapter 246).■

Immunosuppressive Agents

Topical cytotoxic drugs include 5-fluorouracil, mechlorethamine (nitrogen mustard), carmustine (BCNU), bleomycin, and the calcineurin inhibitors tacrolimus and pimecrolimus. Topical 5-fluorouracil interferes with pyrimidine metabolism and action and blocks DNA synthesis. It is used to treat actinic keratosis, superficial basal cell cancer, Bowen's disease, bowenoid papulosis, actinic cheilitis, and warts. Topical use does not cause systemic toxicity, but expected side effects include local irritation, erythema, and pain. Nitrogen mustard and BCNU, which have alkylating agents that inhibit DNA, RNA, and protein synthesis, are used to treat cutaneous T-cell lymphoma (Chapter 190); they can cause cutaneous reactions and myelosuppression, and nitrogen mustard commonly causes a cutaneous hypersensitivity reaction.

Intralesional bleomycin, which disrupts DNA synthesis, has been used to treat warts. Topical tacrolimus (Prograf) and pimecrolimus, immunosuppressive macrolides that act on T lymphocytes to inhibit interleukin-2 (IL-2) transcription, are used for atopic dermatitis, allergic contact dermatitis, psoriasis, and several other inflammatory skin conditions. They frequently cause a burning sensation in the skin; although systemic absorption is minimal, ongoing studies are assessing whether the risk for cancer is increased by their topical use. Systemic immunosuppressives such as methotrexate, azathioprine, thioguanine, hydroxyurea, mycophenolate (CellCept), cyclophosphamide, chlorambucil, rapamycin, and cyclosporine are used for numerous inflammatory or immunologically mediated skin conditions, particularly for widespread psoriasis (Chapter 446) and as glucocorticoid-sparing agents for autoimmune blistering diseases.

Immunomodulatory Therapies

Imiquimod, available as a 5% cream, is an imidazoquinolinamine that has antitumor and antiviral activity. It induces local production of interferon-γ and is used to treat warts and superficial skin cancers. Topical 3% diclofenac in hyaluronic acid, which blocks the induced cyclooxygenase-2 found in precancerous lesions, is approved to treat actinic keratosis. Many systemic immunomodulatory drugs are currently used in dermatology. These include interferons and tumor necrosis factor-α inhibitors such as etanercept, adalimumab, and infliximab (Remicade). In addition, anti–IL-12/23 therapy with ustekinumab is used for psoriasis.■ Anti-CD20 antibodies have been effective in the treatment of autoimmune skin-blistering diseases. Interferon alfa-2b is used both intralesionally and subcutaneously to treat genital warts, high-risk melanoma, Kaposi's sarcoma, hemangiomas, cutaneous T-cell lymphoma, keloids, Behçet's disease, cryoglobulinemia and vasculitis from hepatitis C (Chapter 151), and perhaps basal cell and squamous cell carcinoma. Total interferon doses are generally 3 million IU or less per session, and systemic doses are usually administered 3 days per week. Side effects include flulike symptoms, leukopenia, anemia, and hepatitis. Denileukin diftitox is a fusion protein consisting of a fragment of diphtheria toxin genetically fused to IL-2. It targets IL-2 receptors on the surface of malignant cells and is approved for use in patients with resistant or recurrent cutaneous T-cell lymphoma. Alefacept, which is used to treat psoriasis, affects T cells by blockade of costimulatory signals. Intravenous immunoglobulin, which is used to treat certain autoimmune skin diseases, including pemphigus vulgaris, cicatricial pemphigoid, and dermatomyositis, probably works through Fc receptor modulation and anti-idiotype interactions. Extracorporeal photochemotherapy (photopheresis), which combines 8-methoxypsoralen and ultraviolet A (UVA) irradiation of lymphocytes, is used for Sézary's syndrome, the leukemic form of cutaneous T-cell lymphoma (Chapter 190). Plasmapheresis, used in combination with other immunosuppressive therapies, can remove autoantibodies and immune complexes in patients in whom autoimmune disease or cryoglobulinemia is resistant to other therapies.

OTHER THERAPIES

Phototherapy and Laser

Ultraviolet treatments are given with different wavelengths, depending on the condition and the response to treatment. Currently, clinicians use broadband UVB (290 to 320 nm), narrow-band 311-nm UVB, PUVA (psoralen with 320- to 400-nm UVA), and UVA1 (340 to 400 nm). Both forms of UVB and PUVA are used for psoriasis and vitiligo, but other conditions such as nummular and atopic dermatitis, pruritus resulting from uremia, and cutaneous T-cell lymphoma are treated in this way. High-dose UVA1 is used, mainly in Europe, to treat atopic dermatitis, localized scleroderma, and mastocytosis. PUVA is associated with increased risk for skin cancers, including melanoma. The risks related to long-term UVA therapy are currently unknown, but photoaging is associated with UVA, and there have been reports of an increase in melanoma associated with use of suntanning beds, in which much of the exposure is to UVA. Laser therapy is used to treat vascular lesions such as port-wine stains, tattoos, psoriasis, benign skin tumors, and photodamage, as well as to remove hair. Photodynamic therapy involves activation of a photosensitizer by illumination with visible light, which leads to photochemical tissue destruction or immunomodulation. Photodynamic therapy can be used to treat actinic keratosis, Bowen's disease, and superficial basal cell carcinoma by causing selective tissue necrosis and tumor destruction.

Dermatologic Surgery

Although approaches such as desiccation and curettage can be used for some skin tumors, others require excisional surgery or Mohs' microscopic controlled surgery to ensure complete removal of lesions. If the tumors are recurrent, of a pathologic type that increases the likelihood for recurrence, or large and requiring clearance of the tumor before repair, the Mohs approach can provide rapid documentation of full removal while sparing as much normal tissue as possible. After the margins have been cleared of tumor, flaps and grafts can be used immediately for repair of the resultant defects.

Patients with extensive actinic damage resulting in either large numbers of actinic keratoses or photodamage can be treated with various ablative approaches that use either chemical peels or laser resurfacing with the carbon dioxide laser. Chemical peels can be performed at different depths and intensities, and agents can include glycolic acid, acetic acid, or even phenol. Lasers used to remove sun-induced lentigines include Q-switched lasers such as the neodymium:yttrium-aluminum-garnet, ruby, and alexandrite lasers. Many patients seek treatment of wrinkles with soft tissue augmentation that uses human-derived collagen and hyaluronic acid or with a muscle relaxer, botulinum type A exotoxin.

Hair transplants are a surgical approach to the problem of hair loss. The process includes harvesting hair grafts from the posterior of the scalp and placing the grafts in areas of alopecia.

Sunscreen

Transparent sunscreens absorb photons of light. They are rated by the sun protection factor (SPF), which is determined by the ratio of ultraviolet

exposure needed to cause erythema in protected versus unprotected skin. Most sunscreens work in the UVB range or shorter UVA wavelengths. Examples of UVB-absorptive compounds include aminobenzoates, cinnamates, salicylates, and benzophenones. Short-wavelength UVA-absorptive compounds include benzophenones and anthranilates. The best UVA blocking agent in the United States is avobenzone (Parsol 1789), which can be combined with UVB screens. Some sunscreens are water resistant or waterproof, as determined by the substantivity of the sunscreen, and these agents provide continued protection after sweating or swimming. Sunscreens can cause irritation and, rarely, contact allergic reactions. Physical sunscreens, such as zinc oxide and titanium dioxide, reflect light from the skin and include newer micronized reflecting powders that provide broad-spectrum (UVB and UVA) protection. Sunscreens decrease skin cancers and photodamage. UVB is partially reflected by clothing, and sun-protective clothing can provide substantial protection (Solumbra, SPF of 30).

Cosmetics: Camouflage, Bleaching, and Hair Loss

Patients with numerous skin conditions benefit from camouflage cosmetics, which can also cause contact hypersensitivity. Products such as Dermablend can be blended to match skin colors, are thicker, can cover disfiguring lesions, and can be fixed with powder. Hydroquinones, topical retinoic acid, and azelaic acid (inhibits tyrosinase) are used to treat hyperpigmented conditions such as melasma and lentigines; these agents can be irritating and cause dyspigmentation. Topical minoxidil, 2% (available over the counter) and 5% solutions, are used for androgenic alopecia and alopecia areata. Finasteride, a 5α-reductase inhibitor, is effective in men with androgenic alopecia.

ECZEMAS, PHOTODERMATOSES, PAPULOSQUAMOUS (INCLUDING FUNGAL) DISEASES, AND FIGURATE ERYTHEMAS

HENRY W. LIM

ECZEMA

The more commonly encountered eczemas (Table 446-1) share similar histologic characteristics. However, they have varying degrees of edema within the epidermis (spongiosis) and of infiltration with lymphocytes and macrophages in the superficial dermis.

Nummular Dermatitis

Nummular dermatitis occurs most frequently in patients who are in their 50s to 60s and is usually associated with significant dryness of the skin (xerosis). Both sexes are affected; in temperate climates, this condition is most frequently seen in the winter. The condition appears to be more frequent among Asians. The origin of nummular dermatitis is unclear, although xerosis plays a significant role in its pathogenesis.

Patients usually present with pruritic, coin-shaped, erythematous patches with some scales and occasionally with pinhead-sized vesicles (Fig. 446-1). Lesions may be excoriated and lichenified (i.e., thickened skin with accentuation of skin markings). Legs and arms are commonly affected, and lesions can also occur on the trunk, but facial involvement is uncommon. All patients should be educated about the care of dry skin, such as the use of emollients and moisturizing soaps and avoidance of long, hot showers. Topical corticosteroid ointments (e.g., triamcinolone ointment, 0.1% twice daily for 1 to 2 weeks) are helpful for active lesions, and oral antihistamines (e.g., fexofenadine, 180 mg every morning, and hydroxyzine, 25 to 50 mg at bedtime, as needed) are useful for pruritus. In severe cases, narrow-band ultraviolet B (NB-UVB) phototherapy, a short course of oral corticosteroids (prednisone, 0.5 to 1 mg/kg/day, with a maximal dose of 60 mg/day, for 1 to 2 weeks, then taper in 10 to 14 days) or day hospitalization for intensive topical and ultraviolet (UV) therapy is beneficial.

Dyshidrosis

Dyshidrosis appears as deep-seated, pinhead-sized vesicles, most commonly along the sides of the fingers (Fig. 446-2). Occasionally, the palms and soles may also be involved. Lesions are usually pruritic, associated with xerosis of the surrounding skin. Fissuring of the tip and the side of the fingers frequently occurs. Dyshidrosis is seen in individuals who wash their hands frequently, such as health care and restaurant workers and mothers of young infants. Treatment follows a sequential order: (1) minimizing of hand washing, (2) liberal use of emollients, (3) topical corticosteroid ointments (e.g., fluocinonide ointment, 0.05% twice daily for 2 weeks), and (4) oral antihistamines (e.g., fexofenadine, 180 mg every morning, and hydroxyzine, 25 to 50 mg at bedtime, as needed).

Atopic Dermatitis

Atopic dermatitis is most commonly seen among young children, but severe cases persist into adulthood. In 90% of the patients, the disease starts before the age of 5 years. The prevalence has been estimated at between 15 and 23%. Patients usually present with xerosis, erythematous scaly patches, small

FIGURE 446-2. Dyshidrosis. Deep-seated vesicles and scaliness on fingers.

FIGURE 446-4. Hypopigmentation with fine scales on the forehead and scalp of a patient with seborrheic dermatitis.

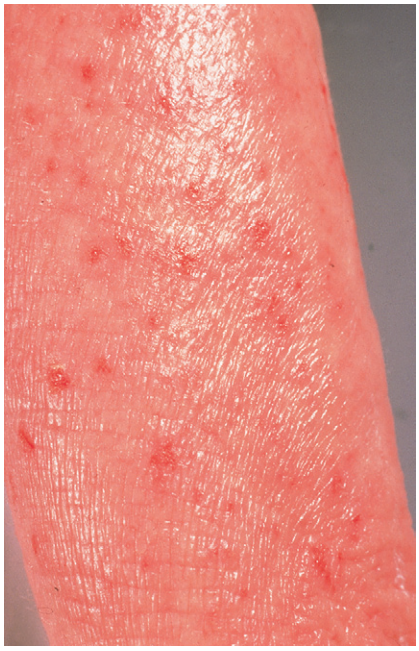

FIGURE 446-3. **Atopic dermatitis.** Note the erythema, excoriation, and lichenification.

vesicles, excoriations, crusting, and, not infrequently, impetiginization (Fig. 446-3). With chronic scratching and rubbing, hyperpigmentation and lichenification occur. Commonly affected sites include the periorbital area and flexor areas such as the neck, antecubital fossa, and popliteal fossa. In severe cases, the entire skin surface may be involved. Diagnosis is made by the typical morphologic features, by the distribution of the lesions, and by a family and personal history of atopy. The therapeutic ladder consists of the following: (1) emollients; (2) topical corticosteroid ointments (e.g., triamcinolone ointment, 0.1% twice daily for 1 to 2 weeks), or topical calcineurin inhibitors (tacrolimus ointment, 0.1% for 3 to 4 weeks, or pimecrolimus cream, 1% for 3 to 4 weeks)■; (3) oral antihistamines (e.g., fexofenadine, 180 mg every morning, and hydroxyzine, 25 to 50 mg at bedtime, as needed); (4) NB-UVB phototherapy; and (5) psoralen and UVA (PUVA). It should be noted that tacrolimus and pimecrolimus have "black box" warnings from the U.S. Food and Drug Administration for their potential association with the development of malignant disease. Although some feel such data are inconclusive, continuous prolonged use (i.e., >2 to 3 months) should be minimized. In patients with recalcitrant cases, day hospitalization, oral prednisone (0.5 to 1 mg/kg/day), cyclosporine (3 to 5 mg/kg/day), and mycophenolate mofetil (1 to 2 g/day) have been successful.

Seborrheic Dermatitis

Seborrheic dermatitis is a common condition that occurs as erythematous patches with fine, greasy-appearing scales, most commonly on the malar area, midforehead, midchest, and scalp (Fig. 446-4). It is common in patients with human immunodeficiency virus (HIV) infection (Chapter 399). The pathogenesis is unknown, although *Pityrosporum ovale* is believed to play a role. The diagnosis is made clinically. Topical corticosteroids (e.g., hydrocortisone cream 2.5%, twice daily for 1 to 2 weeks for facial lesion, fluocinolone acetonide 0.01% solution for scalp, twice daily for 3 to 4 weeks) can rapidly reduce the inflammation; then topical ketoconazole cream, 2% twice daily as needed (or shampoo 2% daily or every other day for the scalp), is safe for long-term treatment.

Allergic Contact Dermatitis and Irritant Contact Dermatitis

Allergic contact dermatitis and irritant contact dermatitis are induced by exogenous agents. Allergic contact dermatitis is a delayed hypersensitivity response to external allergens, whereas irritant contact dermatitis is a nonspecific toxic response to contact irritants. In both conditions, lesions occur in the exposed area, but in patients with severe cases, nonexposed areas may also have milder lesions, especially in allergic contact dermatitis. Patients with allergic contact dermatitis present with erythematous pruritic papules and vesicles. Lesions resolve with fine scales. Postinflammatory hyperpigmentation may be observed, especially in dark-skinned individuals. Histologically, epidermal edema and dermal histiocytic infiltrates are observed. Irritant contact dermatitis manifests with lesions morphologically similar to those of allergic contact dermatitis. However, irritant contact dermatitis is usually associated with a burning sensation rather than with pruritus. Postinflammatory hyperpigmentation is frequently observed. Histologic changes consist of necrotic keratinocytes, epidermal necrosis, and neutrophilic infiltrates. Management includes identification and removal of the offending agent, as well as symptomatic treatments such as topical corticosteroids and oral antihistamines.

PHOTODERMATOSES

Photodermatoses are cutaneous eruptions secondary to exposure to UV or visible radiation (Table 446-2). By convention, electromagnetic radiation in the UV region is divided into UVC (200 to 290 nm), UVB (290 to 320 nm), UVA-2 (320 to 340 nm), and UVA-1 (340 to 400 nm). Visible light extends from 400 to 760 nm. Because UVC emitted by the sun is absorbed by ozone in the stratosphere, UVC does not reach the Earth's surface. UVB, UVA, and less frequently, visible light are the relevant spectra in photodermatoses.

Polymorphic Light Eruption

Polymorphic light eruption, the most common immunologically mediated photodermatosis, occurs in 10 to 20% of the general population. It usually occurs in young adults, has a slight female predominance, and is seen worldwide. Affected individuals are less susceptible to cutaneous photoimmunosuppression and hence have an enhanced response to UV-induced neoantigens in the skin. Lesions usually occur in early spring within a few hours of exposure to sunlight. Lesions can manifest as pinhead papules, papules, papulovesicles, or, less commonly, vesicles (Fig. 446-5); they can also be pruritic. Usually, lesions persist for several days and resolve spontaneously. The condition tends to improve as the sunny season progresses, a phenomenon known as hardening.

FIGURE 446-5. Erythematous papules a few hours after exposure to the sun in a patient with polymorphic light eruption.

TABLE 446-2 SELECTED PHOTODERMATOSES

Polymorphic light eruption
Chronic actinic dermatitis
Solar urticaria
Phototoxicity and photoallergy
Porphyrias

The course is chronic; only 11% of patients have complete resolution of the disease in 16 years and 24% in 32 years. Diagnosis is based on the typical history and morphologic features of the lesion; the diagnosis can be confirmed by the induction of lesions with provocative phototesting. When lesions occur primarily on the face, a diagnosis of lupus must be excluded. Management consists of sun avoidance, the use of broad-spectrum sunscreens, topical corticosteroids, and oral antihistamines. In severe cases, desensitization treatment using NB-UVB or PUVA has been successful. Desensitization is usually performed in early spring by exposing patients to increasing doses of NB-UVB or PUVA three times weekly for 15 treatments.

Chronic Actinic Dermatitis

Chronic actinic dermatitis is a chronic photodermatosis that occurs most commonly in men in their 60s and 70s. It occurs in patients of all ethnic groups, but in the United States, it is more commonly seen in dark-skinned individuals. It is seen in 5 to 17% of patients referred for evaluation of photosensitivity. Chronic actinic dermatitis can evolve from photoallergic contact dermatitis, allergic contact dermatitis, or exposure to a known photosensitizing agent; however, it can also arise de novo. Investigators have postulated that this condition represents a delayed hypersensitivity response to an unidentified antigen.

Patients present with erythematous papules and plaques with superficial scaling and, frequently, with lichenification (Fig. 446-6). The distribution of lesions is primarily on sun-exposed areas, such as the forehead, nose, cheeks, V area of the neck, dorsum of the hands, and forearms. Typically, sun-protected areas, such as the postauricular area, the area underneath the chin, the area above the eyes, and the trunk, are spared. This chronic photosensitivity occurs in the absence of any continued exposure to known photosensitizers. Histologically, one sees a dermal lymphohistiocytic infiltrate; atypical mononuclear cells may be observed. On phototesting, patients have increased sensitivity to UVA, UVB, or visible light, or a combination. In a study of 178 cases, 10% resolved in 5 years and 50% in 15 years. An association with HIV infection (Chapter 399) has been reported.

FIGURE 446-6. Hyperpigmentation and lichenification in a patient with chronic actinic dermatitis. Note sparing of the sun-protected areas of the neck and infra-auricular area.

The diagnosis is based on the patient's history and on the morphologic features and distribution of the lesions. It is confirmed by phototesting.

Management is challenging. During the sunny season, it is critical that patients practice maximal photoprotection, consisting of staying in the shade, using broad-spectrum sunscreens with high SPF, clothing, and wearing a wide-brimmed hat. Other treatment modalities, in approximate sequential order, are topical tacrolimus ointment (0.1%), oral mycophenolate mofetil (1 to 2 g/day), oral cyclosporine (3 to 5 mg/kg/day), and azathioprine (50 to 200 mg/day). Treatment with oral corticosteroids (e.g., prednisone, 1 mg/kg/day) may be needed for acute flare. In recalcitrant cases, the following may be used: PUVA in conjunction with oral corticosteroids or a combination of mycophenolate mofetil, PUVA, and oral corticosteroids.

Solar Urticaria

Solar urticaria occurs worldwide. In photodermatology referral centers, it accounts for 4 to 18% of patients. The mean age at onset is usually in the fourth decade, with a slight female predominance. Patients develop urticaria that appears within minutes of sun exposure and persists for less than 24 hours. Lesions are most commonly induced by visible light, but they can also be induced by UVA or UVB. Similar to polymorphic light eruption, improvement may occur as the summer season progresses (hardening). The diagnosis is confirmed by induction of the lesion after controlled exposure to the appropriate light source. Management consists of photoprotection and the use of oral antihistamines (e.g., fexofenadine, 180 mg every morning, and hydroxyzine, 25 to 50 mg at bedtime). For patients with reactions in the visible light range as determined by phototesting, physical photoprotection is the only effective means because sunscreens do not protect against visible light. In severe cases, graduated exposure to UVA or PUVA is helpful.

Phototoxicity and Photoallergy

The terms *phototoxicity* and *photoallergy* refer to the development of skin lesions after combined exposure to an oral or topical photosensitizer and electromagnetic radiation. Phototoxicity is a nonspecific cutaneous toxic reaction, whereas photoallergy is a delayed hypersensitivity response. For most photosensitizers, the action spectrum for both lies in the UVA range. Most of the phototoxic agents are systemic medications, whereas the most common photoallergens are the various UV filters in sunscreen. In both conditions, patients present with erythematous papules and vesicles confined to sun-exposed areas. Vesicular eruption is distinctly more common in phototoxicity, whereas pruritic eczematous eruption is more common in photoallergy. Histologically, phototoxicity is characterized by necrotic keratinocytes and infiltrates consisting predominantly of neutrophils, whereas photoallergy is characterized by epidermal edema (spongiosis) and lymphohistiocytic dermal infiltrate. The diagnosis is based on a careful history for exposure to photosensitizers combined with the typical morphologic features. Management consists of identification and removal of photosensitizer and the use of topical corticosteroids (e.g., triamcinolone ointment, 0.1% twice daily for 2 weeks) and oral antihistamines (e.g., fexofenadine, 180 mg every morning, and hydroxyzine, 25 to 50 mg at bedtime as needed [Chapter 445]).

Porphyrias

The most common cutaneous porphyria is porphyria cutanea tarda, in which patients present with skin fragility and blister formation on sun-exposed areas, most commonly the dorsum of the hands and the forearms (Fig. 446-7; Chapter 217). Patients usually have periorbital hypertrichosis and, less frequently, periorbital mottled hyperpigmentation and hypopigmentation. Sclerodermoid skin changes can occur in both sun-exposed and sun-protected areas. The defective enzyme is uroporphyrinogen decarboxylase. Porphyria cutanea tarda is associated with excessive alcohol intake, exposure to estrogens, hepatitis C infection (Chapter 151), HIV infection (Chapter 399), and hemochromatosis (Chapter 219). Patients invariably have an elevated level of ferritin and frequently have elevated liver enzyme values.

The diagnosis is suggested by the typical clinical appearance and is confirmed by the characteristic porphyrin profile (elevated levels of 8-, 7-, 6-, 5-, and 4-carboxyl porphyrins in the urine and isocoproporphyrin in feces; Chapter 217). Management consists of avoidance of precipitating factors (alcohol, iron-containing vitamins, estrogen-containing birth control pills) and weekly phlebotomy. In patients who are anemic (e.g., those with HIV infection), low-dose hydroxychloroquine (200 mg/week) is beneficial.

PAPULOSQUAMOUS (INCLUDING FUNGAL) DISEASES

Common papulosquamous diseases are listed in Table 446-3.

Psoriasis

EPIDEMIOLOGY

Psoriasis is the most commonly recognized papulosquamous disease. It occurs in 2 to 3% of the general population, with considerable variation in different parts of the world. It affects male and female patients equally. Approximately one third of the patients have a positive family history. Psoriasis has a bimodal peak of onset, at age 22.5 years and again at age 55 years. The onset of psoriasis before the age of 15 years is associated with a higher prevalence of positive family history of psoriasis and with more severe disease.

PATHOBIOLOGY

Psoriasis involves the innate and adaptive immune systems, with abnormal keratinocyte proliferation. Factors playing a role in the pathogenesis include activation of antigen-presenting cells and development of T_H1 and T_H17 cells. Mediators include interleukin-12 (IL-12), IL-23, tumor necrosis factor-α (TNF-α), and interferon-γ. Investigators have postulated that, in genetically susceptible individuals, exposure to precipitating factors such as infections (e.g., streptococcal or HIV infections), stress, or physical injury results in activation of T cells and generation of cytokines, followed by influx of neutrophils and subsequent release of inflammatory mediators, which lead to the development of cutaneous lesions.

Psoriasis has a complex, polygenetic inheritance. Susceptibility genes include *PSORS1* to *PSORS9*, although *PSORS1*, mapped to chromosome 6p21.3, is now considered a major locus for susceptibility to psoriasis.

CLINICAL MANIFESTATIONS

Psoriasis can involve the skin, scalp, and nails. Skin lesions are characterized by erythematous macules, papules, or plaques that are usually covered with silvery scales (Fig. 446-8). On removal of the scales, pinpoint bleeding may be observed (the Auspitz sign), a finding reflecting the proliferation of blood vessels in the superficial dermis. Nail involvement includes pittings, yellowish macules underneath the nail plate ("oil drop" sign), and thickening of the nail (onychodystrophy) (Fig. 446-9). Minor injury to the skin can result in the development of psoriatic lesions (Koebner's phenomenon). The association of psoriasis with HIV infection (Chapter 399) has been well documented.

Several distinct forms of psoriasis are recognized. *Psoriasis vulgaris,* the most common type, appears as a persistent erythematous scaly papule and plaque most commonly on elbows, knees, and scalp. *Guttate psoriasis* usually occurs after viral or bacterial (most commonly streptococcal) infection; it appears as small, erythematous, scaly papules scattered over a large area of the body in a raindrop distribution (*guttate* means "droplike"). *Inverse psoriasis* refers to psoriasis that occurs in skinfold areas such as the groin, axilla, and inframammary folds. It appears as an erythematous, somewhat shiny patch; because of the constant friction in the involved areas, scales are usually absent. *Erythrodermic psoriasis* appears as widespread erythroderma with fine silvery scales. *Palmoplantar psoriasis* manifests as keratotic scaly patches and plaques on the palms and soles, very frequently with accompanying fissures. *Pustular psoriasis of von Zumbusch* is a rare variant of psoriasis occurring with

FIGURE 446-9. Thickening and crumbling of the nail plate (onychodystrophy) in a patient with psoriasis. Note the erythematous patches with silvery scales in the periungual area.

generalized pustules that are 2 to 3 mm in diameter and associated with the onset of fever.

Five to 30% of patients with psoriasis may also have psoriatic arthritis, which may precede the appearance of cutaneous lesions (Chapter 273); 95% of these patients present with peripheral asymmetrical oligoarthritis involving the interphalangeal joints of the hands and feet, while 5% have exclusively axial or skeletal disease. Psoriatic arthritis has been associated with HLA-B57, although some studies have also reported HLA-Cw6 in more than 50% of all persons with this disease. Psoriasis is associated with ulcerative colitis, lymphoma, the metabolic syndrome, heart disease, depression, smoking, and alcohol consumption.

DIAGNOSIS

In most cases, the diagnosis of psoriasis can be made based on the history and physical examination alone. However, in patients with erythrodermic psoriasis, other causes of generalized erythroderma (including pityriasis rubra pilaris, drug eruption, and cutaneous T-cell lymphoma) must be excluded.

TREATMENT Rx

Therapy includes topical medications, UV-based treatment, and systemic drugs. For mild disease, topical therapy with topical corticosteroids (e.g., triamcinolone ointment, 0.1% twice daily for 1 to 2 weeks), calcipotriene cream (0.005%, twice daily as needed), or tazarotene gel (0.05%, once or twice daily as needed), used alone or in combination, is effective. In patients who have widespread lesions, NB-UVB is the best option, whereas PUVA should be considered for patients in whom NB-UVB therapy has failed. For patients with recalcitrant disease, oral medications such as methotrexate (7.5 to 15 mg/week), acitretin (25 to 50 mg/day), cyclosporine (3 to 5 mg/kg/day), hydroxyurea (1 g/day), and mycophenolate mofetil (1 to 2 g/day) have all been used with success.

Biologic agents, because of their cost, are usually reserved for when conventional therapy has failed or is contraindicated (Table 446-4). TNF-α inhibitors include etanercept, a human TNF receptor/immunoglobulin G1 (IgG1) fusion protein; infliximab, a chimeric mouse anti-TNF-α antibody; and adalimumab, a human IgG1 anti-TNF-α antibody. A CD2 antagonist is alefacept, a protein that is fused to IgG and that contains the binding site of lymphocyte function–associated antigen-3, which binds to CD2 markers on the surface of memory T cells. Efalizumab, an anti-CD11a humanized monoclonal antibody, has been taken off the market because of increased incidence of progressive multifocal leukoencephalopathy Ustekinumab, a fully human monoclonal antibody against the p40 subunit of IL-12 and IL-23 (at 45 or 90 mg, repeated at 1 month) is efficacious and appears to be superior to etanercept for moderate-to-severe psoriasis.[2,3]

FIGURE 446-10. Pityriasis rubra pilaris. Note the erythematous orange plaques with islands of sparing.

TABLE 446-4 BIOLOGIC AGENTS FOR PSORIASIS

BIOLOGIC AGENTS	DOSE/DURATION	MONITORING	SIDE EFFECTS
TNF-α INHIBITORS			
Etanercept (Enbrel)	50 mg SC twice a week for 12 wk, then 50 mg SC weekly indefinitely	PPD CBC, LFT	Injection site reaction, infection
Infliximab (Remicade)	5-10 mg/kg IV at weeks 0, 2, 6, then every 8 wk indefinitely	PPD CBC, LFT	Infusion reaction, sepsis, lupus-like syndrome, aplastic anemia (rare)
Adalimumab (Humira)	80 mg SC at week 0, 40 mg at wk 1, then 40 mg every 2 wk indefinitely	PPD CBC, LFT	Injection site reaction, infection
ANTI-CD2			
Alefacept (Amevive)	15 mg IM weekly for 12-16 wk; consider a second course after a 12-wk interval	CD4	Infection
ANTI–IL-12/23			
Ustekinumab (Stelara)	SC at weeks 0, 4, then every 12 wk <100 kg: 45 mg; >100 kg: 90 mg indefinitely	PPD	Infection

CBC = complete blood count; IM = intramuscularly; IV = intravenously; LFT = liver function test; PPD = purified protein derivative; SC = subcutaneously; TNF = tumor necrosis factor.

Pityriasis Rubra Pilaris

EPIDEMIOLOGY

Pityriasis rubra pilaris occurs equally in men and women; the incidence ranges from 1 in 5000 new dermatology patients in Great Britain to 1 in 50,000 in India. This disease most frequently occurs as the acquired form, although a familial form (autosomal dominant with variable expression) also occurs. Sixty percent of patients have adult-onset disease, with peak incidences in the first, second, and fifth to sixth decades. Abnormal vitamin A metabolism has been postulated as a possible cause.

CLINICAL MANIFESTATIONS

Clinically, patients present with erythematous to orange papules and plaques on all parts of the body (Fig. 446-10). Characteristically, skin appears normal between these lesions ("islands of sparing"). Erythema, hyperkeratosis, and fissures of the palms and soles are common; when severe, these lesions result in functional impairment. Many patients have follicular keratotic papules on the dorsa of the fingers and occasionally on the elbows as well as on the wrists. The nails are yellow and thickened, with distal splinter hemorrhages. In adult patients, the condition typically starts on the face and moves to the lower extremities; in the juvenile form, it usually starts in the lower half of the body. Ectropion may occur, and pruritus is observed in approximately

FIGURE 446-11. Large erythematous oval patch (herald patch) of pityriasis rosea accompanied by smaller erythematous patches.

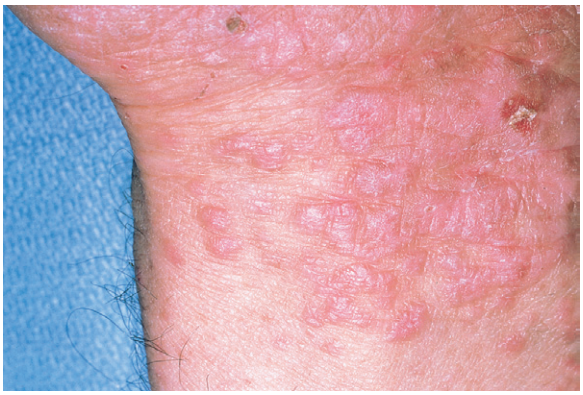

FIGURE 446-12. Erythematous flat-topped papules on the wrist of a patient with lichen planus.

20% of patients. In contrast to psoriasis, arthritis is uncommon. Pityriasis rubra pilaris has been associated with HIV infection (Chapter 399).

DIAGNOSIS

Definitive diagnosis can usually be made based on the clinical presentations and by the characteristic histologic findings of alternating vertical and horizontal parakeratosis in the stratum corneum.

TREATMENT Rx

The most effective treatment is with oral retinoids (acitretin, 25 to 50 mg/day for 2 to 4 months). Methotrexate (7.5 to 15 mg/week), either as a monotherapy or in combination with oral acitretin, is also beneficial. Other options include PUVA or cyclosporine (3 to 5 mg/kg/day). For all patients, topical emollients should be used as needed, and topical keratolytic agents, such as ammonium lactate lotion 12%, twice daily as needed, are helpful as adjunctive therapy.

Pityriasis Rosea

EPIDEMIOLOGY AND PATHOBIOLOGY

The incidence of pityriasis rosea has been reported as 3 to 30 per 1000 patients. It occurs in all ethnic groups, most commonly in the third and fourth decades of life, with a slight female predominance. The cause is not known, and a possible association with human herpesvirus types 6 and 7 has been reported.

CLINICAL MANIFESTATIONS

In 50 to 90% of patients, pityriasis rosea starts with a primary lesion (herald patch), which is an erythematous, scaly, oval patch a few centimeters in diameter. This lesion is usually followed within a few days by smaller erythematous scaly patches on the trunk, less commonly on the proximal extremities (Fig. 446-11). As a rule, the palms and soles are spared. The distribution of the eruption, especially on the back, tends to follow the lines of cleavage of the skin, with a resulting "Christmas tree" distribution. Lesions are most commonly asymptomatic, although they may be mildly pruritic. The eruption is self-limited and resolves within 6 to 8 weeks. In rare instances, lesions may persist.

DIAGNOSIS

The diagnosis can usually be made clinically. The most important differential diagnosis is secondary syphilis, which, in contrast to pityriasis rosea, usually involves the palms and soles. In many instances, a rapid plasma reagin test is advisable to exclude syphilis.

TREATMENT Rx

Treatment is primarily symptomatic, including topical corticosteroids and oral antihistamines. NB-UVB phototherapy or PUVA should be reserved for patients with severe, recalcitrant cases.

Lichen Planus

EPIDEMIOLOGY

Lichen planus occurs most commonly in patients between 30 and 60 years of age. Women are affected more frequently than men and tend to be somewhat older at the onset of disease. The prevalence in the general population is about 1%.

PATHOBIOLOGY

Histologically, lichen planus is characterized by dense lymphocytic infiltrate at the dermal-epidermal junction. The infiltrates consist of predominantly T cells, a finding suggesting the pathogenic role of cell-mediated immunity. Because lichen planus or lichen planus–like eruptions can occur after exposure to drugs or chemicals (e.g., color film developer), the role of drugs and chemicals in inducing a T-cell–mediated response against the epidermis has been postulated. Lichen planus may be associated with hepatitis C infection (Chapter 151).

CLINICAL MANIFESTATIONS

Clinically, patients usually present with erythematous to violaceous flat-topped papules, often with white lacy lines (Wickham's striae) on the wrists, forearms, and genitalia (Fig. 446-12). *Oral lichen planus* occurs as white papules and plaques with a reticulated appearance, most commonly along the bite line on the buccal mucosa. Erosion may occur, and genital mucosa may also be involved. *Hypertrophic lichen planus* usually occurs on the lower extremities as lichenified, violaceous plaques, probably secondary to chronic rubbing and scratching of the lichen planus lesions. *Erosive lichen planus* occurs as erosion usually surrounded by violaceous discoloration at the periphery; this variant tends to occur more commonly on the feet. *Bullous lichen planus* occurs as vesicles or bullae arising from a preexisting lesion of lichen planus. *Lichen planopilaris* occurs as violaceous papules and plaques involving the scalp, most prominently surrounding the hair follicles; it progresses to scarring alopecia. *Lichen planus actinicus*, a variant of lichen planus occurring most commonly in the Middle East, tends to occur on the sun-exposed areas such as the forehead; it occurs as papules or plaques with minimally elevated rolled edges. *Atrophic lichen planus* resembles typical lichen planus lesions but with a central area of superficial atrophy. *Lichen planus of the nails* causes a thinning of the nail with longitudinal ridges; it may progress to complete loss of the nail plate (pterygium formation).

DIAGNOSIS

The diagnosis can be made by clinical appearance. It is confirmed by the characteristic histologic findings of infiltration by lymphocytes at the dermal-epidermal junction.

TREATMENT Rx

Several treatment options are available. Topical corticosteroids (e.g., triamcinolone ointment, 0.1% twice daily for 2 to 4 weeks) are helpful in patients with limited disease. Hypertrophic lichen planus can be treated with topical corticosteroids (fluocinonide 0.05% ointment, twice daily for 2 to 4 weeks), with occlusion at night, or with interlesional corticosteroid injections (triamcinolone suspension, 3 to 5 mg/mL). A 6- to 8-week course of oral corticosteroid is helpful in patients with widespread lichen planus. NB-UVB phototherapy

FIGURE 446-13. Scaly papules and plaques on the palm of a patient with secondary syphilis.

or PUVA is helpful for widespread conditions. Oral acitretin (25 to 50 mg/day) or systemic cyclosporine (3 to 5 mg/kg/day) has been used with good success in some patients. Oral lesions can be treated with topical corticosteroids (triamcinolone 0.1% paste, twice daily for 2 to 3 weeks), topical retinoids (tretinoin gel 0.01%, twice daily for 3 to 4 weeks), or cyclosporine solution (100 mg/mL, 1 mL, twice daily, swish and spit). Painful erosive lesions in the mouth and genital area are best treated with oral prednisone in combination with mycophenolate mofetil (1 to 2 g daily). Without treatment, cutaneous lesions resolve in approximately 1 year, whereas oral and hypertrophic lesions tend to be much more chronic, persisting for an average of 4.5 years and 8.5 years, respectively.

Lichen Nitidus

Lichen nitidus is a rather uncommon condition that usually occurs in children or young adults. The incidence has been estimated to be 3.4 cases per 10,000 population. It is more commonly observed in dark-skinned individuals. The cause is unclear, and no infectious agent has been identified.

The lesions are 1- to 2-mm, shiny, skin-colored discrete papules, sometimes with fine scales on their surface, occurring most commonly on the genitalia or forearms and occasionally on the trunk. A generalized form has rarely been reported. Lesions are usually asymptomatic. Histologically, one sees a dense lymphocytic infiltrate in the superficial dermis and at the dermal-epidermal junction. In contrast to lichen planus, in which the infiltrate tends to involve the entire section of the skin, the infiltrate in lichen nitidus tends to be much more focal and localized.

The diagnosis usually can be confirmed from the typical clinical appearance and the characteristic histologic changes. The condition tends to remit spontaneously in a few years, so therapy, with topical corticosteroids (e.g., triamcinolone ointment, 0.1% twice daily for 2 weeks) and oral antihistamines (e.g., fexofenadine, 180 mg every morning, and hydroxyzine, 25 to 50 mg at bedtime, as needed) should be reserved for symptomatic cases only.

Secondary Syphilis

Lesions of secondary syphilis typically occur 1 to 2 months after the development of a primary chancre lesion (Chapter 327). However, up to 25% of patients may not remember having a chancre. Once the eruption occurs, it lasts for 1 to 3 months.

Clinically, secondary syphilis may appear as erythematous macules ("roseola syphilitica"), erythematous to hyperpigmented oval or circular papules and plaques covered with scales, or a maculopapular eruption. Nodular eruption may also occur occasionally. The lesions tend to be widespread, and the palms and soles are very frequently involved (Fig. 446-13). The diagnosis is made based on the history, physical examination, and a positive rapid plasma reagin test. Skin biopsy shows the proliferation of endothelial cells in the dermis and a dense dermal infiltrate containing many plasma cells. Intramuscular benzathine penicillin or procaine penicillin is the recommended treatment, with oral doxycycline or tetracycline as alternatives.

FIGURE 446-14. Erythematous patches with fine scales in a patient with large plaque parapsoriasis.

Pityriasis Lichenoides

Pityriasis lichenoides occurs as erythematous papules that may be minimally pruritic and covered with scales, scattered on all parts of the body. In the acute form (pityriasis lichenoides et varioliformis acuta [PLEVA]), the central part of the lesions develops vesicles, pustules, and hemorrhages, with eventual crusting of the lesions. The patient may have mild constitutional symptoms of fever and malaise. The chronic form (pityriasis lichenoides chronica [PLC]) occurs as asymptomatic erythematous to hyperpigmented papules and plaques covered with fine scales; the trunk and extremities are common sites. Histologically, both PLEVA and PLC are characterized by dense lymphocytic infiltrates in the dermis, with CD8 lymphocytes predominating in PLEVA and CD4 lymphocytes in PLC.

PLEVA usually resolves in a few months, although it can persist. PLC usually lasts for a few years. Both disorders affect patients of all ages, with a slight male predominance.

Treatment generally follows a sequential order: (1) topical corticosteroids (e.g., triamcinolone ointment, 0.1% twice daily for 1 to 2 weeks) and antihistamines, (2) tetracycline (1 to 2 g/day), or erythromycin (1 to 2 g/day), (3) NB-UVB phototherapy (three times weekly for 8 to 10 weeks with increasing doses of NB-UVB) or PUVA, and (4) methotrexate (7.5 to 15 mg/week).

Parapsoriasis

The two common variants of parapsoriasis are large plaque parapsoriasis and small plaque parapsoriasis. The peak incidence is in the fifth decade, although rare cases may begin in childhood. Large plaque parapsoriasis appears as oval to circular, erythematous to hyperpigmented macules and patches with fine scales and superficial atrophy (crinkling atrophy) scattered on all parts of the body (Fig. 446-14). These lesions are usually larger than 5 cm. Although lesions may be minimally pruritic, they are usually asymptomatic. Large plaque parapsoriasis is considered by some to be a less aggressive variant of mycosis fungoides (see later). Small plaque parapsoriasis appears as circular to oval erythematous to hyperpigmented patches or minimally elevated plaques, with lesions smaller than 5 cm in diameter and usually covered with fine scales. Digitate dermatosis is a distinct variant of small plaque parapsoriasis in which lesions appear along the lines of cleavage, usually on the lateral aspect of the trunk in the shape of fingerprints. Histologically, large plaque parapsoriasis is characterized by a dermal lymphocytic infiltrate, which may extend into the epidermis, whereas small plaque parapsoriasis is characterized by spongiotic dermatitis, with a mild superficial lymphocytic infiltrate in the dermis. In up to one third of patients, large plaque parapsoriasis may evolve into mycosis fungoides. As a result, treatment of large plaque parapsoriasis is similar to that of early-stage mycosis fungoides: high-potency topical corticosteroids, topical nitrogen mustard, NB-UVB phototherapy, and PUVA. By comparison, patients with small plaque parapsoriasis have a benign course, and management of small plaque parapsoriasis should be symptomatic only, with emollients, topical corticosteroids, and NB-UVB phototherapy.

Mycosis Fungoides

Mycosis fungoides is a variant of cutaneous T-cell lymphoma (Chapter 191). The four types of cutaneous manifestations are patch, plaque, tumor, and

FIGURE 446-15. Hyperpigmented patches in a patient with mycosis fungoides.

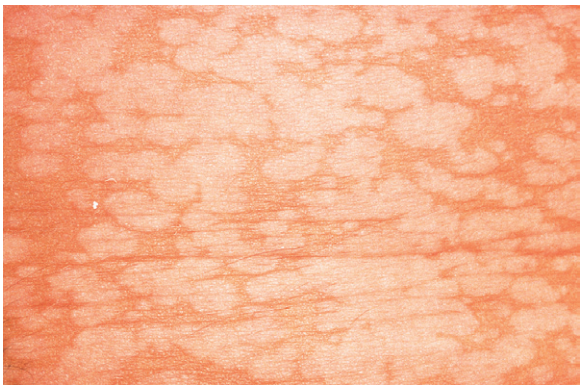

FIGURE 446-16. Hypopigmented patches of tinea versicolor.

erythrodermic. The patch stage of mycosis fungoides manifests as patches with fine "cigarette paper" wrinkling of the epidermis. The patches can be skin colored or minimally erythematous; hyperpigmented or hypopigmented lesions are frequently seen in dark-skinned patients. The patches can vary from a few millimeters to a few centimeters in diameter; they are more common on sun-protected areas such as the buttocks (Fig. 446-15). The patches are usually asymptomatic, although they occasionally may be mildly pruritic. Lesions may be present for years. As the disease progresses, some of the patches may become more indurated and may evolve into more elevated plaques. Nodular lesions may occur in patients without any patch or plaque lesions, although more commonly these lesions occur in conjunction with patches and plaques. Erythrodermic mycosis fungoides occurs as a generalized erythroderma with significant scaling and pruritus. Hyperkeratosis of the palms and soles, as well as fissuring of hands and feet, are quite common. In dark-skinned patients, mycosis fungoides may appear as hypopigmented patches.

The diagnosis is confirmed by histologic demonstration of atypical mononuclear cells both in the epidermis and in the dermis, as well as immunophenotypic markers showing predominance of CD4 cells in the infiltrate. Therapy for mycosis fungoides generally follows a sequential order: (1) topical nitrogen mustard (i.e., mechlorethamine, 10 mg in 60 mL of water, applied daily until lesions resolve, then taper), or NB-UVB, each of which can be combined with topical corticosteroids (e.g., triamcinolone ointment, 0.1% twice daily for 1 to 2 months); (2) PUVA; (3) topical retinoids (e.g., bexarotene gel, 1% once to four times daily, until lesions resolve); and (4) one of the following: oral bexarotene (300 mg/m^2/day for 2 to 4 months) or interferon-α (3 to 9 million units subcutaneously 3 times weekly for 2 to 4 months). Erythrodermic disease is most effectively treated with extracorporeal photopheresis.

Dermatophytoses

Fungal infections that occur as papulosquamous eruptions include tinea corporis, tinea manuum, tinea cruris, and tinea pedis. Tinea corporis presents as a polycyclic erythematous scaly patch that has elevated borders and consists of papules and sometimes pustules. As the lesion progresses, the border advances centrifugally. The trunk is the most common site. Tinea cruris has similar morphologic features, except it is located in the inguinal folds and expands centrifugally from the folds. In men, the scrotum is usually spared. Tinea manuum presents as an erythematous scaly patch with an advancing active border, usually located on the dorsum of the hands, or it may occur as diffuse scaly patches with mild hyperkeratosis involving part or the entire surface of the palm and palmar aspect of the fingers. Tinea pedis also has two clinical manifestations: it can occur as scaly macerated lesions with erythema in the toe webs or as patchy or diffuse scaliness on the sole extending to the medial and lateral aspect of the foot (moccasin distribution). The latter presentation can be associated with diffuse scaliness of one but not both palms, a condition known as the "one-hand, two-feet syndrome." The diagnosis can be confirmed by examination of skin scrapings using 10% potassium hydroxide preparation or by fungal culture. Treatment consists of topical or oral antifungal medications (e.g., clotrimazole cream, 1%, twice daily for 2 to 4 weeks, or terbinafine, 250 mg for 2 to 12 weeks), depending on the site involved.

Tinea Versicolor

Tinea versicolor is a fungal infection of the skin caused by *Malassezia furfur*. It occurs in otherwise healthy young individuals, especially in warm and moist environments during the summer. Clinically, it appears as macules and patches with very fine scales; the color can be hypopigmented, skin colored, minimally erythematous, or light brown (Fig. 446-16). The patches start as perifollicular macules, with the midchest and midback the most common sites. As the lesions progress, hypopigmentation of the skin may also occur. The lesion usually is asymptomatic. The diagnosis is confirmed by the characteristic appearance of the fungal elements on a 10% potassium hydroxide preparation: grapelike clusters of yeast and short, septate branching hyphae ("spaghetti and meatballs" appearance). Treatment is with 2.5% selenium sulfide shampoo (applied for 10 minutes then wash off, 5 times weekly for 4 to 6 weeks), topical antifungal preparations (e.g., clotrimazole cream, 1% twice daily for 4 weeks), or a 1- to 3-day course of oral ketoconazole (200 mg/day).

TABLE 446-5 FIGURATE ERYTHEMAS

Erythema annulare centrifugum
Erythema gyratum repens
Erythema chronicum migrans

FIGURATE ERYTHEMIAS

These conditions appear as erythematous circular or polycyclic plaques with central clearing and, frequently, centrifugally migrating border (Table 446-5). Occasionally, fine scaling may also be observed. The extremities are the most common sites. The diagnosis can frequently be made by the typical history and morphologic features.

Erythema annulare centrifugum is most commonly idiopathic; however, it can also be a manifestation of a hypersensitivity response to medications. Management includes identification of a precipitating agent (if possible) and treatment with topical or systemic corticosteroids. *Erythema gyratum repens* occurs as concentric erythematous plaques with fine scales, resembling a wood-grain pattern. This unusual form of figurate erythema has been associated with malignant hematologic diseases and with carcinomas of the breast, lung, gastrointestinal tract, prostate, and cervix. Treatment of the underlying malignant disease results in the resolution of the skin lesion in a few months. *Erythema chronicum migrans*, which is a cutaneous manifestation of Lyme disease and is caused by the spirochete *Borrelia burgdorferi* (Chapter 329), appears as a concentric ring of erythema that progresses centrifugally from the site of a tick bite. Occasionally, it may appear as a circular erythematous patch. The diagnosis is made by a history of a tick bite, the characteristic cutaneous lesion, or elevated serum antibodies to *B. burgdorferi*. Management is the same as for Lyme disease.

MACULAR AND PAPULAR EXANTHEMS

An exanthem is an acute generalized eruption of the skin, and there are two major types: scarlatiniform eruptions and morbilliform eruptions. Scarlatiniform eruptions consist of confluent blanching erythema; their name was derived from their similarity to the eruption of scarlet fever (Table 447-1). Morbilliform eruptions consist of erythematous macules and papules; they are named for their resemblance to the measles eruption. Morbilliform eruptions can be caused by exposure to medications (Chapter 448) or viral infections.

Scarlatiniform Eruptions

SCARLET FEVER

Scarlet fever is caused by infection of the ears, nose, throat, and skin with toxin-producing β-hemolytic streptococci (Chapter 298). It most commonly occurs in children after streptococcal wound infections, burns, and upper respiratory tract infections. Occasional cases of scarlet fever can also be caused by *Staphylococcus aureus* (Chapter 296), *Haemophilus influenzae* (Chapter 308), and *Clostridium* species (Chapter 304). The rash is due to a circulating toxin that induces local production of inflammatory mediators and alteration of cutaneous cytokines. Patients may have an abrupt onset of fever, headache, vomiting, malaise, chills, and sore throat. The mucous membranes are usually erythematous with petechiae, and the tongue commonly has a white membrane. Red, exudative tonsils are present with pharyngeal infections. The skin eruption appears after the fever and is characterized by fine erythematous papules, first on the upper part of the trunk and then in a more general distribution. The face is flushed, and circumoral pallor is seen. This eruption lasts 4 to 5 days, followed by fine desquamation, the extent and duration of which are related to the severity of the eruption. Treatment is 1.2 million units of benzathine penicillin G given intramuscularly or oral penicillin VK, 1000 mg twice daily for 10 days. Most patients recover after 4 to 5 days, and the rash usually resolves completely over a period of several weeks.

TOXIC SHOCK SYNDROME

DEFINITION

Toxic shock syndrome is an acute febrile illness caused by toxin-producing strains of *S. aureus* (Chapter 296) or, less commonly, *Streptococcus* species (toxic shock–like syndrome [Chapter 298]).

PATHOBIOLOGY

Most cases of staphylococcal toxic shock syndrome or streptococcal toxic shock–like syndrome occur in young healthy persons aged 20 to 50 years. These toxins cause massive release of tumor necrosis factor-α and interleukin-1, cytokines that mediate fever, rash, hypotension, tissue injury, and shock.

CLINICAL MANIFESTATIONS

The hallmarks of the disease are fever, rash, hypotension, and involvement of multiple organs, including the lungs, kidneys, liver, and gastrointestinal tract. Desquamation of the palms and soles follows onset of the illness by 1 to 2 weeks. There is diffuse macular erythema with flexural accentuation, mucous membrane erythema, and severe conjunctival involvement. Blood cultures are positive in 5 to 15% of patients with staphylococcal toxic shock syndrome and approximately 50% of those with streptococcal toxic shock-like syndrome.

TREATMENT

Rx

Treatment is supportive and includes hydration, vasopressors, appropriate antibiotics, and drainage of infected sites. Patients with staphylococcal toxic shock should be treated with intravenous vancomycin to cover methicillin-resistant staphylococci, 1 g every 12 hours for 10 to 15 days, with dose adjustment based on creatinine clearance. Patients with streptococcal toxic shock should be treated with both intravenous penicillin G, 3 to 4 million units every 4 hours, and intravenous clindamycin, 600 to 900 mg every 8 hours for 10 to 15 days, followed by oral therapy. Double antibiotic coverage is the standard of care for streptococcal toxic shock syndrome because this infection is characterized by extremely large numbers of stationary bacteria and penicillin alone is not effective in this scenario inasmuch as penicillin-binding proteins are not expressed during the stationary group phase of streptococci. Silver sulfadiazine cream may lead to increased toxin production; therefore, mupirocin ointment should be used for infected sites.

PROGNOSIS

The mortality rate in patients with staphylococcal toxic shock syndrome is 5 to 15%, whereas that for streptococcal toxic shock–like syndrome may be five times higher.

KAWASAKI DISEASE

EPIDEMIOLOGY

Kawasaki disease, a systemic vasculitis of unknown etiology, occurs in children of all races but is up to 20 times more common in North East Asians than in whites. Although primarily an illness of children younger than 5 years, Kawasaki disease also occurs in adults. Its epidemiologic and clinical manifestations imply that an infection is the cause, but bacterial, viral, and serologic studies have yet to confirm such an etiology.

CLINICAL MANIFESTATIONS

The clinical hallmarks are fever lasting up to 2 weeks, with spikes to 40° C (104° F), and a toxic-appearing patient. During the acute phase, the polymorphic eruption may be scarlatiniform, urticarial, morbilliform, or targetoid. Desquamation occurs in the perianal area 2 days after the onset of fever and on the extremities 2 to 3 weeks later. Patients often have hemorrhagic, dry fissured lips, conjunctival injection, a "strawberry tongue," and cervical

lymphadenitis. Myocarditis and coronary artery aneurysms may develop in untreated patients, so prompt diagnosis is critical. Other findings include arthralgias and arthritis, urethritis, aseptic meningitis, pneumonitis, and diarrhea.

DIAGNOSIS

Despite the lack of specific diagnostic tests for this syndrome, the typical skin eruption accompanied by myocarditis is characteristic.

TREATMENT Rx

Recommended therapy in the acute phase of Kawasaki disease is a single infusion of 2 g/kg of intravenous gamma globulin. When this therapy is given within 5 to 10 days after the onset of fever, 85 to 90% of patients will become afebrile within 36 hours, and the risk of developing coronary artery aneurysms is significantly reduced. During the subacute and convalescent phase, acetylsalicylic acid is usually given at 3 to 8 mg/kg for 6 to 8 weeks. The optimal salicylate regimen for Kawasaki disease remains uncertain, and there are no controlled trials to prove that aspirin reduces coronary artery aneurysms.

FIGURE 447-1. Reticulate macular erythema on the thigh of a patient with erythema infectiosum.

Morbilliform Eruptions

MEASLES

Measles is caused by a paramyxovirus (Chapter 375) that infects respiratory epithelium and is highly transmissible. The incubation period is 7 to 14 days. The prodrome consists of cough, coryza, and conjunctivitis. The enanthem, or Koplik's spots, predates the exanthem by 1 to 2 days and lasts 2 to 4 days. These blue-white spots surrounded by a red halo appear on the buccal mucosa and are pathognomonic for measles. The exanthem begins on the fourth or fifth day as papules on the face and behind the ears; it then spreads to the trunk and extremities. Measles is diagnosed on clinical grounds. Active immunization with live attenuated virus has dramatically reduced the incidence of measles infection (Chapter 17) and is the most important preventive measure. Treatment consists of supportive care, with attention to maintaining good hydration.

RUBELLA

Rubella is an RNA virus of the Togaviridae family (Chapter 376). Infection with this virus leads to an illness involving the skin, lymph nodes, and occasionally the joints, primarily in young children. The disease is spread by nasal droplet infection and has an incubation period of 14 to 21 days. Patients are most contagious when the rash is erupting. In children there may be no prodrome; in adults, however, fever, sore throat, and rhinitis may be present. The exanthem begins as pink macules and papules on the face that spread to the trunk and extremities; it lasts 1 to 3 days. Generalized tender lymphadenopathy, especially the suboccipital, postauricular, and cervical nodes, is the hallmark of rubella. In normal children and adolescents, the diagnosis is made clinically, and laboratory work is unnecessary. If the diagnosis is questioned, a rising immunoglobulin M (IgM) antibody titer over a 2-week period indicates recent infection. No treatment exists, and the disease is usually self-limited. Rest and fluids are appropriate. The best protection is vaccination given with measles and mumps vaccine (i.e., MMR) at 12 to 15 months and again at 4 to 6 years (Chapter 17).

ERYTHEMA INFECTIOSUM

Erythema infectiosum is an exanthem caused by human parvovirus B19 (Chapter 379). It has a 4- to 14-day incubation period and is spread by aerosolized respiratory droplets. Acute infection leads to the production of IgM antibodies and the formation of immune complexes, which are deposited in the skin and joints. Bright red erythema appears abruptly over the cheeks. Within 1 to 4 days, an erythematous morbilliform eruption occurs on the extremities; it fades within several days to a reticulate pattern (Fig. 447-1). There may also be malar erythema or a reticulate eruption on the extremities. Exposure of adults to parvovirus B19 leads to an acute polyarthropathy of the hands, wrists, knees, and ankles. Parvovirus B19 can interfere with erythropoiesis (Chapter 168) and can cause aplastic crisis in patients with sickle cell disease (Chapter 166). The diagnosis is clinical, and further testing is not generally necessary. Erythema infectiosum is usually a benign, self-limited disease.

ROSEOLA

Roseola (exanthem subitum) is caused by human herpesvirus 6 (Chapter 382). Virus replication occurs in leukocytes and salivary glands. Early invasion of the central nervous system (CNS) may lead to seizures. The classic patient is a healthy 9- to 12-month-old with an abrupt onset of high fever (40° C [104° F]) lasting 3 days. Febrile seizures occur in 15% of cases. Its rapid defervescence is striking, with the onset of a generalized pink morbilliform exanthem. The eruption lasts 2 days and consists of pink papules or blanchable macular erythema. The lack of symptoms during the febrile phase and appearance of the exanthem as the fever subsides help with the diagnosis, but rubella and measles must also be considered. In an immunocompromised child or adult, there is usually an abrupt onset of fever, malaise, and sometimes CNS involvement. Virus isolation, seroconversion (IgM), or detection of viral DNA sequences in peripheral blood mononuclear cells can confirm the diagnosis. No antiviral therapy is available for roseola, and treatment is supportive. Practically all immunocompetent patients recover from roseola without sequelae, but chronic infection with multisystem complications may develop in immunocompromised patients.

Papular Eruptions

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a cutaneous infection caused by a large DNA poxvirus (Chapter 380) that affects both children and adults. Firm, smooth, umbilicated papules, usually 2 to 6 mm in diameter, are present in groups or widely disseminated on the skin and mucosal surfaces. Patients infected with human immunodeficiency virus (HIV) may have hundreds of lesions, and some lesions can be larger than 15 mm (Chapter 399). The diagnosis is made on clinical grounds. Molluscum contagiosum is self-limited, with the goal of treatment being destruction of the lesions. Commonly used treatments are all topical and include cryotherapy with liquid nitrogen, curettage, cantharidin, podophyllin, and tretinoin.

WARTS

Warts are benign proliferations of skin and mucosa caused by human papillomaviruses (HPVs) (Chapter 381). More than 150 types of HPV have been identified. Certain types of HPV occur at particular anatomic sites; however, warts of any HPV type may be found at any site. Variants include common warts, genital warts, flat warts, and deep palmoplantar warts. Common warts, known as verruca vulgaris, are hard papules that range in size from 1 mm to more than 1 cm with a rough scaly surface (Fig. 447-2) and can occur anywhere on the body. Warts are transmitted by direct contact, and disruption of the epithelial barrier is a predisposing factor. HPV subtypes 6, 11, 16, 18, 31, and 35 may be associated with malignancies (Chapter 381). Malignant transformation, although uncommon, can occur in patients with genital warts or in immunocompromised patients. Infection is confined to

the epithelium and does not result in systemic viral dissemination. The diagnosis is made on clinical grounds. Viral DNA identification by Southern blot hybridization is used to identify specific HPV subtypes. All therapies are methods of physical destruction of the skin where the virus is located because there are no specific anti-HPV medications. Common topical therapies include in-office treatment with liquid nitrogen, cantharidin, or podophyllin, as well as prescription-strength tretinoin or imiquimod. Over-the-counter liquid nitrogen is neither as cold nor as effective as in-office treatment.

Purpuric Eruptions

Purpura occurs when red blood cell extravasation leads to visible hemorrhage in the skin (Table 447-2). Petechiae (<3 mm) and purpura (>3 mm) may be nonpalpable or palpable. When the condition is severe, petechiae and purpuric lesions may become confluent and form ecchymoses larger than 1 cm.

NONPALPABLE PURPURA

Dermal Causes

Frequent causes of nonpalpable purpura include solar purpura, steroid purpura, and Schamberg's disease. Solar purpura, caused by chronic sun exposure and aging, is usually found on the forearms. Steroid purpura, which is due to prolonged use of topical or systemic steroids, can occur in any location (Chapter 34). Both conditions are caused by changes in the dermal connective tissue surrounding blood vessels. Schamberg's disease, or pigmented purpuric dermatosis, is a capillaritis with yellow-brown macules and petechiae on the lower part of the legs. This capillaritis occurs as a result of red blood cell extravasation secondary to perivascular lymphocyte inflammation.

Systemic Causes

Systemic causes of nonpalpable purpura include idiopathic thrombocytopenic purpura (Chapter 175), abnormal platelet function as a result of renal or hepatic insufficiency (Chapters 132 and 157) or thrombocytosis as seen in myeloproliferative diseases (Chapter 169), and clotting factor abnormalities (Chapter 177). Fragility of the blood vessels, especially the capillaries, is found in Ehlers-Danlos syndrome (Chapter 268), scurvy (Chapter 220), and systemic amyloidosis (Chapter 194).

Thrombi

Thrombus formation within skin blood vessels also leads to purpura in patients with disseminated intravascular coagulation (Chapter 178), thrombotic thrombocytopenic purpura (Chapter 175), monoclonal cryoglobulinemia (Chapter 193), and drug reactions to warfarin (Chapter 37). Disseminated intravascular coagulation may be caused by infectious agents (bacterial, particularly meningococcemia, viral, or rickettsial) and by malignancies such as leukemia (Chapter 178). Purpura fulminans is a type of disseminated intravascular coagulation associated with fever and hypotension; it is usually found in children after a bacterial or viral infection. Widespread purpura and hemorrhagic bullae can be seen in disseminated intravascular coagulation and purpura fulminans (Fig. 447-3). Thrombotic thrombocytopenic purpura (Chapter 175) is manifested as fever, purpura, renal failure, microangiopathic hemolytic anemia, and neurologic disease. Monoclonal cryoglobulinemia may be associated with leukemia, lymphoma, multiple myeloma, and Waldenström's macroglobulinemia. Mixed cryoglobulinemia is frequently associated with hepatitis C infection (Chapter 151). Widespread purpura, along with ulcerations limited to the lower extremities or fingers and toes, can occur. Skin biopsy specimens may reveal intracapillary deposits of precipitated cryoglobulins. Disease can be worsened by exposure to cold. The vessels of the lungs, brain, and kidneys may be involved. Warfarin necrosis of the skin (Chapter 37) is an uncommon reaction that occurs between the third and tenth day of therapy and is characterized by painful erythematous to purpuric plaques in which hemorrhagic bullae develop. The most common sites include the breasts, thighs, and buttocks. The onset of disease is unrelated to the dose of warfarin, and continued warfarin therapy does not alter the course of the disease.

Emboli

Cholesterol emboli are found in the lower extremities of patients with severe atherosclerosis as a result of occlusion of small- and medium-caliber arteries

FIGURE 447-4. Palpable purpura. Leukocytoclastic vasculitis commonly causes raised purpuric and ulcerated lesions on the legs.

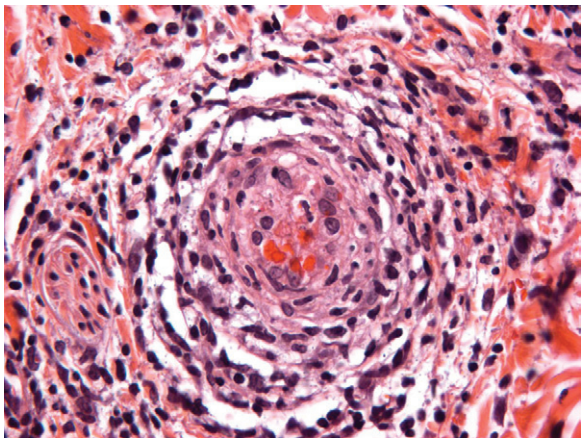

FIGURE 447-5. Leukocytoclastic vasculitis. Histologic evaluation reveals a smudged blood vessel in the dermis with neutrophils, neutrophilic dust, and red blood cells.

by cholesterol crystals (Chapters 80 and 127). Cholesterol emboli are triggered by vascular procedures or thrombolytic therapy, but they can also occur spontaneously. Other sources of emboli that may cause petechiae or purpura include fat emboli occurring after major injury (Chapters 98 and 112), tumor emboli from atrial myxomas (Chapter 60), emboli from infective endocarditis (Chapter 76), or nonbacterial thrombotic endocarditis (Chapters 60 and 187).

PALPABLE PURPURA

Vasculitis

Palpable purpura results from inflammatory damage to cutaneous blood vessels. Leukocytoclastic vasculitis, which is manifested as palpable purpura (Fig. 447-4), may be idiopathic or associated with sepsis, drug reactions, connective tissue diseases, cryoglobulinemia, hepatitis B or C infection, or underlying malignancies. Appropriate evaluation of patients with palpable purpura should always include histopathologic evaluation to confirm the diagnosis. Skin biopsy specimens from patients with leukocytoclastic vasculitis reveal angiocentric inflammation with endothelial cell swelling, fibrinoid necrosis of blood vessel walls, a neutrophilic cellular infiltrate with fragmentation of nuclei (karyorrhexis or leukocytoclasia) around and within blood vessel walls, and extravasated red blood cells (Fig. 447-5). Fresh skin biopsy specimens processed for direct immunofluorescence reveal deposits of immunoglobulins and complement in blood vessel walls. Once the diagnosis is confirmed, routine blood tests (including testing of renal and liver function) and urinalysis should be performed in all patients, whereas specialized tests should be targeted to specific patients with suggestive findings. If an etiologic agent can be identified and treated, the vasculitis will often resolve. Patients with idiopathic leukocytoclastic vasculitis can be treated with oral colchicine (0.6 mg twice daily), oral dapsone (up to 200 mg once daily), or in the most severe cases, immunosuppressive agents such as mycophenolate mofetil (up to 45 mg/kg for as long as the disease is active), azathioprine (up to 2.5 mg/kg for as long as the disease is active, as guided by the thiopurine methyltransferase level), or cyclophosphamide (up to 2.5 mg/kg for as long as the disease is active).

Henoch-Schönlein purpura is a leukocytoclastic vasculitis that affects children and young adults; it is often preceded by an upper respiratory infection with associated fever, arthralgias, abdominal pain, and renal vasculitis (Chapter 123). Direct immunofluorescence reveals IgA deposits in dermal blood vessels.

Urticarial or hypocomplementemic vasculitis (Chapter 278) is characterized by urticarial lesions that last longer than 24 hours; arthritis, facial, and laryngeal edema; and low serum complement levels. In some patients, systemic lupus erythematosus (Chapter 274) may develop. In polyarteritis nodosa (Chapter 278), vasculitis of the arterial blood vessels leads to ischemia of the skin. Skin lesions usually include ulcerated nodules and ecchymoses.

Cutaneous Emboli

In addition to vasculitis, cutaneous emboli can also lead to the development of palpable purpura. Infectious emboli (Chapter 76) can be caused by gram-negative cocci, gram-negative rods, *Rickettsia* species, and in immunocompromised patients, *Candida* species and opportunistic fungi. Acute meningococcemia (Chapter 306) occurs after an upper respiratory tract infection and is associated with headache, fever, meningitis, hypotension, and disseminated intravascular coagulation. The embolic lesions, which are found on the trunk and lower extremities, can range from 1 mm up to several centimeters. Disseminated gonococcal infection (Chapter 307) is accompanied by fever, arthralgias, tenosynovitis, and a small number of vesiculopustules with purpura or hemorrhagic necrosis over the distal ends of the extremities. Rocky Mountain spotted fever (Chapter 335) is a tick-borne disease characterized by headache, fever, chills, photophobia, and myalgias. The cutaneous eruption starts acrally and spreads centripetally as small, erythematous, blanchable macules that evolve into petechiae, palpable purpura, and ecchymoses. Ecthyma gangrenosum is manifested as erythematous papules and plaques in which central purpura and hemorrhagic necrosis develop; *Pseudomonas aeruginosa* (Chapter 314) is the most common organism, but *Klebsiella* species (Chapter 314), *Escherichia coli* (Chapter 312), and *Serratia* species (Chapter 315) have also been implicated. In immunocompromised patients, ecthyma gangrenosum may develop as a result of infection with *Candida* species or opportunistic fungi.

VESICULOBULLOUS DISEASES

Vesicles are clear, fluid-filled lesions measuring less than 5 mm; bullae or blisters are clear, fluid-filled lesions larger than 5 mm. Vesiculobullous lesions in the skin may be caused by immunologically mediated mechanisms, hypersensitivity reactions, metabolic disorders, inherited genetic defects, and infections (Table 447-3).

Immunologically Mediated Blistering Diseases

BULLOUS PEMPHIGOID

DEFINITION

Bullous pemphigoid is an autoimmune blistering disease that occurs in elderly people. Tense blisters and urticarial plaques occur on the flexor surfaces of the arms and legs, axilla, groin, and abdomen (Fig. 447-6).

PATHOBIOLOGY

IgG autoantibodies bind to the epidermal basement membrane and activate complement, which attracts inflammatory cells. These inflammatory cells release proteases that degrade basement membrane proteins and lead to blister formation. Histology reveals a subepidermal blister with an eosinophilic infiltrate. Direct immunofluorescence shows linear deposits of IgG and C3 at the basement membrane. Indirect immunofluorescence studies using salt-split skin demonstrate circulating IgG antibodies that bind to the epidermal side.

TREATMENT Rx

Treatment is dictated by the degree of involvement and the rate of progression of the disease. The ultrapotent topical steroid clobetasol (10 to 30 g per day), applied to the skin of patients with bullous pemphigoid until 15 days after disease control is obtained and then tapered over 4 months, is effective, is superior to oral corticosteroid treatment, and is associated with fewer side effects than higher dose clobetasol in patients with both moderate and severe

FIGURE 447-6. Bullous pemphigoid. Tense subepidermal bullae are seen on an erythematous base.

FIGURE 447-7. Herpes gestationis. Multiple tense blisters and erosions on an erythematous base are present.

disease.[2] Nevertheless, the practicality of such potent topical steroids is controversial, and many experts use oral prednisone, 1 mg/kg in an early morning daily dose, as a foundation of therapy for patients with generalized bullous pemphigoid. Other treatments include tetracycline (500 mg four times daily), dapsone (up to 150 mg daily), azathioprine (up to 2.5 mg/kg as guided by the thiopurine methyltransferase level), methotrexate (up to 15 mg weekly), mycophenolate mofetil (35 to 45 mg/kg divided into two daily doses), and cyclophosphamide (up to about 2.5 mg/kg). The duration of therapy with all of these medications varies, depending on the activity of the disease. Left untreated, bullous pemphigoid generally persists for months to years. Spontaneous remissions and exacerbations occur. The mortality rate is relatively low, even without treatment.

Herpes Gestationis

Herpes gestationis is a rare autoimmune dermatosis of pregnancy. Despite the name, herpes gestationis has no relationship to herpesvirus infection. Most patients have intense pruritus. Periumbilical urticarial plaques progress to vesicles and blisters. The eruption spreads peripherally (Fig. 447-7), typically sparing the face, palms, soles, and mucous membranes. IgG autoantibodies are produced against bullous pemphigoid antigen II, which is critical in epidermal-dermal adhesion. Antibody binding triggers an immune response leading to blister formation. Histology reveals a subepidermal blister, and direct immunofluorescence shows linear C3 deposits at the basement membrane.

Corticosteroids are the mainstay of therapy. Patients with mild disease are treated with moderate- to high-potency topical corticosteroids, such as 0.05% fluocinonide ointment applied twice daily to affected areas, whereas patients with extensive disease usually require systemic corticosteroids, such as prednisone, 1 mg/kg given once daily as an early morning dose. Disease clears within 1 to 2 weeks after initiation of treatment. There is an increased risk for premature delivery and birth of infants who are small for gestational age, suggesting that these women should be managed by obstetricians experienced in high-risk pregnancies.

Mucous Membrane Pemphigoid

DEFINITION

Mucous membrane pemphigoid, previously called cicatricial pemphigoid, is a group of subepithelial blistering diseases that involve the mucosal surfaces. Patients have blisters of the oral, ocular, nasopharyngeal, laryngeal, anogenital, and esophageal mucosa that heal with scarring, which causes the major morbidity associated with the disease.

PATHOBIOLOGY

There are several subgroups of mucous membrane pemphigoid. Some patients have circulating IgG autoantibodies that bind to the dermal side of salt-split skin and recognize laminin 5. A second subgroup includes patients who have pure ocular disease and IgG antibodies directed against β_4 integrin. A third subgroup has mucosal disease and skin lesions. The fourth variant includes patients with oral disease but without skin disease. Histology reveals a subepidermal blister with an inflammatory cell infiltrate. Direct immunofluorescence shows linear IgG, IgA, and C3 deposits at the basement membrane. Indirect immunofluorescence reveals circulating IgG or IgA antibodies, or both.

TREATMENT

Rx

Treatment is dictated by the extent, severity, and location of disease; it ranges from topical corticosteroids, such as 0.05% fluocinonide ointment applied twice daily to affected areas under occlusion in patients with only oral disease, to prednisone, 1 mg/kg given once daily as an early morning dose, and cyclophosphamide, up to 2.5 mg/kg given as an early morning dose for up to 2 years, for severe ocular disease. Management teams should include ophthalmologists, otolaryngologists, dermatologists, and internists for patients with severe disease. Patients with both circulating IgG and IgA antibodies tend to have more severe disease.

FIGURE 447-8. Dermatitis herpetiformis. The elbow of a patient has eroded erythematous papules and papulovesicles.

FIGURE 447-9. Pemphigus vulgaris. The lower lip of a patient has confluent erosions with scattered crusting.

PROGNOSIS

Mucous membrane pemphigoid is a chronic disease. Untreated ocular disease can result in blindness.

EPIDERMOLYSIS BULLOSA ACQUISITA

Epidermolysis bullosa acquisita is an acquired autoimmune blistering disease that generally occurs in middle age. There are two types of skin lesions: noninflammatory acral blisters that heal with scarring and milia formation and widespread inflammatory vesiculobullous disease.

PATHOBIOLOGY

Epidermolysis bullosa acquisita is characterized by IgG autoantibodies that target collagen VII, the major protein of anchoring fibrils. These autoantibodies alter dermal-epidermal adhesion and lead to blister formation. Histology reveals a subepidermal blister containing few inflammatory cells when mechanobullous lesions are sampled or a neutrophil-rich infiltrate when inflammatory blisters are sampled. Direct immunofluorescence reveals linear IgG deposits at the basement membrane. Indirect immunofluorescence shows circulating IgG autoantibodies that bind the dermal side of salt-split skin.

TREATMENT Rx

Epidermolysis bullosa acquisita is a chronic disease that is very difficult to treat. Dapsone (at doses up to 150 mg daily), colchicine (0.6 mg twice daily), azathioprine (up to 2.5 mg/kg as guided by the thiopurine methyltransferase level), or cyclophosphamide (2.5 mg/kg given as an early morning dosage) alone or along with prednisone (60 mg given once daily as an early morning dose) is only occasionally successful. Cyclosporine at doses of up to 5 mg/kg, extracorporeal photopheresis, and intravenous immunoglobulin (at doses of 2 gm/kg given monthly) have been used successfully in patients with severe disease. Because of nephrotoxicity, cyclosporine should be reserved for crisis management of patients who have severe disease and are experiencing a major flare.

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is an immune-mediated vesicular disease that usually occurs in young to middle-aged patients. Skin lesions are extremely pruritic, grouped vesicles and erosions located on the scalp, posterior of the neck, and extensor surfaces of the elbows, knees, and buttocks (Fig. 447-8). Most patients have a subclinical gluten-sensitive enteropathy (Chapter 142) that is reversible with a gluten-free diet. Diet alone can sometimes control the skin disease, with clearance of the cutaneous granular IgA deposits at the basement membrane. Biopsy specimens of skin lesions reveal dermal papillary neutrophilic microabscesses. Direct immunofluorescence shows dermal papillary granular IgA deposits in all patients. Most patients with dermatitis herpetiformis have circulating IgA antibodies directed against tissue transglutaminase. Dermatitis herpetiformis can be treated with dapsone, up to 200 mg daily given chronically. Dermatitis herpetiformis is a lifelong disease.

LINEAR IMMUNOGLOBULIN A BULLOUS DERMATOSIS

Linear IgA bullous dermatosis is an acquired autoimmune blistering disease of the skin. The primary lesions are papulovesicles, and involvement of the oral mucous membranes is common. The disease occurs throughout adulthood. Deposition of IgA antibody specific for a portion of bullous pemphigoid antigen II leads to complement activation and neutrophil chemotaxis. Proteolytic enzymes are released, destroy the dermal-epidermal junction, and cause blister formation. Histology reveals a subepidermal vesicle or cleft with neutrophil predominance. Direct immunofluorescence shows linear deposits of IgA at the basement membrane. Indirect immunofluorescence demonstrates circulating IgA antibodies. Most patients respond to dapsone, up to 200 mg daily, given chronically. Patients whose disease is not controlled with dapsone may benefit from the addition of oral prednisone, 1 mg/kg once daily as an early morning dose. The disease tends to be chronic in adults, but the childhood version (called chronic bullous disease of childhood) may run a several-year course and then remit.

PEMPHIGUS

DEFINITION

Pemphigus refers to a group of autoimmune blistering intraepidermal diseases of the skin and mucous membranes that are most common in middle age.

CLINICAL MANIFESTATIONS

Patients with pemphigus vulgaris have flaccid blisters and erosions in the oropharynx (Fig. 447-9), trunk, head, neck, and intertriginous areas. Pemphigus foliaceus is accompanied by erythema, scaling, and crusting of the face, scalp, and upper part of the trunk. Patients with paraneoplastic pemphigus have ocular and oral blisters and erosions along with skin lesions resembling erythema multiforme and an associated underlying malignancy that is generally lymphoreticular in origin (Chapter 187).

PATHOBIOLOGY

Autoantibodies in pemphigus vulgaris target desmoglein III, and autoantibodies in pemphigus foliaceus target desmoglein I. Circulating antibodies in paraneoplastic pemphigus recognize a complex of proteins, including desmoplakin I and II, bullous pemphigoid antigen I, envoplakin, periplakin, and desmoglein I and III.

DIAGNOSIS

Skin biopsy specimens from patients with pemphigus vulgaris reveal suprabasilar acantholysis, whereas pemphigus foliaceus biopsy specimens demonstrate subcorneal acantholysis. Biopsy specimens of paraneoplastic pemphigus show suprabasilar acantholysis and dyskeratotic keratinocytes with basal cell vacuolization.

Direct immunofluorescence demonstrates cell surface deposits of IgG in patients with pemphigus vulgaris and foliaceus, whereas indirect immunofluorescence reveals circulating IgG antibodies that recognize molecules on the epidermal cell surface. Patients with paraneoplastic pemphigus have circulating and tissue-bound IgG antibodies that are indistinguishable from those in pemphigus vulgaris and that also recognize the cell surface of simple epithelia, including the liver and heart.

TREATMENT Rx

Treatment regimens depend on the patient's age, the degree of involvement, the rate of disease progression, and the subtype of pemphigus. Systemic corticosteroids (e.g., oral prednisone, 1 mg/kg once daily as an early morning dose) are required for the treatment of patients with pemphigus vulgaris, whereas topical corticosteroids (e.g., 0.05% fluocinonide ointment applied twice daily to affected areas) may occasionally control pemphigus foliaceus. One course of intravenous immunoglobulin (400 mg/kg/day for 5 days) appears to be a safe and effective treatment for patients whose disease is resistant to steroids.■ Other agents include dapsone (up to 200 mg daily), hydroxychloroquine (administered at less than 6 mg/kg of lean body mass divided into two daily doses), mycophenolate mofetil (35 to 45 mg/kg/day divided into two daily doses), azathioprine (up to 2.5 mg/kg as guided by the thiopurine methyltransferase level), cyclophosphamide (up to 2.5 mg/kg given as an early morning dose), and rituximab (four weekly doses of 375 mg/m^2). The duration of therapy with each of these medications varies according to the level of disease activity. Although the use of steroid-sparing agents is supported by clinical experience, few controlled studies have demonstrated their benefit. For paraneoplastic pemphigus caused by benign tumors such as Castleman's disease (Chapter 191), tumor removal is often curative. Patients with associated malignant tumors have recalcitrant disease, although there are occasional successes with pulse corticosteroids (methylprednisolone, 1000 mg given daily for 3 consecutive days), pulse cyclophosphamide (500 to 1000 mg given monthly for 6 months to 1 year, often along with varying doses of prednisone), immuno-apheresis, immunoablative high-dose cyclophosphamide (50 mg/kg/day for 4 days), and rituximab (four weekly doses of 375 mg/m^2).

PROGNOSIS

Before the availability of corticosteroids, 60 to 90% of patients with pemphigus vulgaris died, whereas the mortality rate has now decreased to the 5 to 10% range. The prognosis of patients with paraneoplastic pemphigus is related to the type of associated neoplasm. Patients with benign tumors usually experience clearance of their lesions after tumor resection, whereas those with malignant tumors generally have a poor prognosis.

Hypersensitivity Reactions That Cause Blisters

ERYTHEMA MULTIFORME

DEFINITION

Erythema multiforme is an acute blistering eruption that occurs in all age groups. Erythema multiforme minor is localized, with minimal or no mucosal involvement. Erythema multiforme major, also known as Stevens-Johnson syndrome, is a more severe mucosal and skin disease characterized by signs and symptoms reminiscent of serum sickness (Chapter 46).

CLINICAL MANIFESTATIONS

Toxic epidermal necrolysis is at the most severe end of the erythema multiforme spectrum. The primary lesions of erythema multiforme minor are erythematous macules and edematous papules with vesicular centers that become dusky violet. Target or iris lesions are found on extensor surfaces of the extremities and spread centripetally (Fig. 447-10). The skin lesions of Stevens-Johnson syndrome resemble those of erythema multiforme minor but are likely to be generalized and show confluent erythema with urticarial and purpuric lesions. Erosions of two or more mucosal surfaces occur in Stevens-Johnson syndrome and may include hemorrhagic crusting of the lips, ulceration of the ocular mucosa, and genital involvement. Patients with erythema multiforme major have a 1- to 14-day prodrome that includes fever, cough, sore throat, vomiting, and diarrhea. Patients with toxic epidermal necrolysis may have a similar prodrome, rapidly followed by generalized macular erythema that progresses to confluent erythema with skin tenderness. Large blisters follow soon afterward, and then skin sloughing occurs as the large blisters break and leave denuded skin.

PATHOBIOLOGY

Common etiologic associations of erythema multiforme include infections such as herpes simplex (Chapter 382) (especially recurrent erythema multiforme minor), *Mycoplasma pneumoniae* (Chapter 325), and drug reactions (Chapter 262). Sulfonamides, penicillins, barbiturates, carbamazepine, phenytoin, allopurinol, and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most common drugs implicated in Stevens-Johnson syndrome and toxic epidermal necrolysis.

FIGURE 447-10. Erythema multiforme. Target or "bull's-eye" annular lesions with central vesicles and bullae are characteristic of erythema multiforme.

DIAGNOSIS

The diagnosis of erythema multiforme is clinical.

TREATMENT Rx

Chronic antiviral treatment with acyclovir (400 mg twice daily for 6 months) decreases outbreaks in a subset of patients with recurrent erythema multiforme minor. Treatment of erythema multiforme major is otherwise nonspecific, with attention to fluid and electrolyte balance and eye disease being critical. If a drug is suspected, it must be withdrawn. Systemic corticosteroid treatment is contraindicated in Stevens-Johnson syndrome. Treatment of toxic epidermal necrolysis is very difficult, but uncontrolled studies suggest that intravenous immune globulin (2 to 3 g/kg over a period of 2 to 5 days) may improve the prognosis.

PROGNOSIS

Erythema multiforme minor usually subsides within 2 to 3 weeks. Erythema multiforme major takes 3 to 6 weeks to clear and has less than a 5% mortality rate. Toxic epidermal necrolysis has a mortality rate approaching 30%, and patients are best managed in an intensive care or burn unit.

Metabolic Disorders That Cause Blisters

PORPHYRIA CUTANEA TARDA

Porphyria cutanea tarda is caused by deficient activity of the heme synthetic enzyme uroporphyrinogen decarboxylase (Chapter 217). The fragility of sun-exposed skin leads to erosions and bullae, which are worst on the dorsal surface of the hands (Fig. 447-11), forearms, and face. Healing of crusted erosions and blisters leaves scars, milia, and hyperpigmented and hypopigmented atrophic patches. Hypertrichosis is common and most florid over the temporal and malar areas. Urinary porphyrin levels are abnormally high. Histology reveals a subepidermal blister with minimal dermal infiltrate, and direct immunofluorescence demonstrates immunoglobulin and complement deposition in dermal capillaries and at the basement membrane. Phlebotomy is the standard treatment, and the goal is to reduce serum ferritin to the lower limit of the normal range. Another treatment option is oral hydroxychloroquine at a dose (200 mg twice weekly until the disease is under control) that is much lower than that used for photoprotective indications. Alcohol and estrogen use should be discontinued because they can cause the disease to flare.

PSEUDOPORPHYRIA

Pseudoporphyria is a bullous eruption that mimics porphyria cutanea tarda clinically and histologically without porphyrin abnormalities. Many medications can cause pseudoporphyria, including propionic acid–derivative NSAIDs (e.g., naproxen, diflunisal, ketoprofen, nabumetone, oxaprozin, and mefenamic acid), furosemide, tetracycline, fluoroquinolones, amiodarone, cyclosporine, dapsone, etretinate, and flutamide. The prognosis is good for patients with pseudoporphyria after the offending agent has been discontinued. However, resolution of the disease may take several months. In patients with chronic renal failure treated by hemodialysis, true porphyria cutanea tarda or pseudoporphyria may develop and is very difficult to treat.

FIGURE 447-11. Porphyria cutanea tarda. A blister and erosions are present on the dorsal surface of the hand.

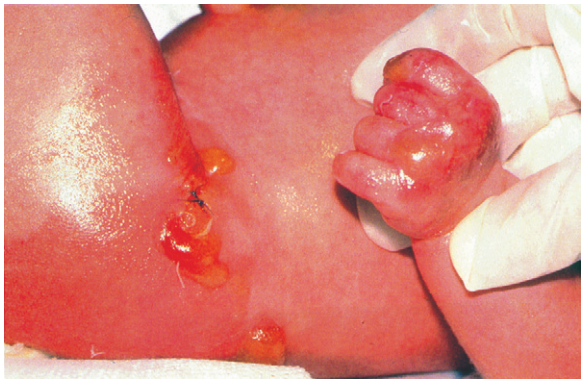

FIGURE 447-12. Epidermolysis bullosa simplex. Tense blisters and erosions are present on the trunk and extremities of a newborn.

FIGURE 447-13. Bullous impetigo. Multiple blisters are present on the trunk of this patient.

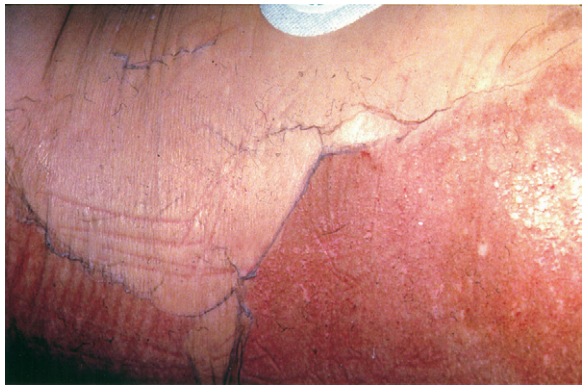

FIGURE 447-14. Staphylococcal scalded skin syndrome. Confluent erythema with exfoliation of skin is seen on the trunk.

DIABETES MELLITUS

Distal extremity blisters may occasionally develop in patients with diabetes mellitus (Chapter 236). There is no correlation between the development of blisters and the severity, duration, or complications of diabetes. The mechanism of blister formation is not understood.

Inherited Genetic Disorders That Cause Blisters

Epidermolysis bullosa is a group of inherited bullous disorders characterized by blister formation in response to mechanical trauma. Subtypes include epidermolysis bullosa simplex (intraepidermal skin separation) (Fig. 447-12), junctional epidermolysis bullosa (skin separation in the lamina lucida), and dystrophic epidermolysis bullosa (sublamina densa separation). Infancy is an especially difficult time, and epidermolysis bullosa may be accompanied by blistering that is complicated by infection and sepsis. Many patients with junctional epidermolysis bullosa have severe disease that can lead to death, usually secondary to infection, and metastatic squamous cell carcinoma may develop in some patients with recessive dystrophic epidermolysis bullosa and can also lead to death. In contrast, epidermolysis bullosa simplex, milder forms of junctional epidermolysis bullosa, and dominant dystrophic epidermolysis bullosa do not usually affect life expectancy. Epidermolysis bullosa simplex is caused by mutations of the genes coding for keratins 5 and 14. Junctional epidermolysis bullosa has a variable molecular etiology, and mutations in genes coding for laminin 5 subunits, bullous pemphigoid antigen I, α_6 integrin, and β_4 integrin have been demonstrated. Dystrophic epidermolysis bullosa is caused by mutations of the type VII collagen gene. Epidermolysis bullosa is a lifelong disease. Some subtypes, especially the milder forms, improve with age. No medications are known to correct the underlying molecular defects, but gene therapy is being actively pursued.

Infectious Diseases That Cause Blisters

IMPETIGO

Impetigo is a bacterial infection of the superficial layers of the epidermis. Bullous impetigo is caused by *S. aureus* (Chapter 296), and nonbullous impetigo is caused by group A β-hemolytic streptococci (Chapter 298). Bullous impetigo is manifested as vesicles and bulla (Fig. 447-13). Lesions are common on the face but may appear anywhere. Nonbullous impetigo is characterized by fragile vesicles or pustules that rupture and leave honey-colored crusted papules or plaques, especially near the nose and mouth and on the extremities. Lesions develop on normal or traumatized skin or are superimposed on preexisting conditions, including scabies, varicella, or atopic dermatitis. The causative agent of bullous impetigo is coagulase-positive *S. aureus,* which produces exfoliatins A and B. The toxins cause cleavage within or below the stratum granulosum. Impetigo is diagnosed clinically. Culture and sensitivity studies are recommended if topical or oral treatment is ineffective. Oral antibiotics, including dicloxacillin (500 mg four times daily for 7 days) or cephalexin (500 mg three times daily for 7 days), are used for extensive disease or in patients refractory to topical mupirocin. Gentle débridement of crusts is recommended. Lesions resolve after 7 to 10 days of treatment. Acute glomerulonephritis (Chapter 123) develops in 2 to 5% of young children with nonbullous impetigo, usually within 10 days after the skin lesions appear.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Staphylococcal scalded skin syndrome is a blistering disease caused by an exotoxin produced by *S. aureus* (Chapter 296). It is most common in young children but may occur in adults who have renal insufficiency or are immunocompromised. The site of the staphylococcal infection is usually extracutaneous. Staphylococcal scalded skin syndrome is manifested as a sudden onset of fever and tender, blanchable erythema. It starts on the central part of the face, neck, and intertriginous areas and rapidly generalizes. The palms, soles, and mucous membranes are spared. Flaccid blisters occur within 1 to 2 days and soon exfoliate in large sheets, with superficially denuded skin remaining (Fig. 447-14). The disease must be distinguished from toxic epidermal necrolysis by skin biopsy. In staphylococcal scalded skin syndrome, there is an upper epidermal blister, whereas toxic epidermal necrolysis causes a dermal-epidermal blister. Patients with the most severe staphylococcal scalded skin syndrome should be treated with intravenous nafcillin or oxacillin, 2 g every 4 to 6 hours for 10 to 14 days. If the patient is found to have

methicillin-resistant staphylococci, vancomycin, 1 g every 12 hours (with dose adjustment based on creatinine clearance), should be given for 10 to 14 days. Patients with mild disease may be treated with oral dicloxacillin, 500 mg four times daily for 10 to 14 days, unless the staphylococcal isolate is methicillin resistant, in which case the choice of antibiotics should be guided by the results of sensitivity testing.

HERPES SIMPLEX VIRUS INFECTION

PATHOBIOLOGY

Herpes simplex virus (HSV) infection (Chapter 382) may be caused by type 1 or type 2 HSV. The hallmark of HSV infection is its ability to establish latent infection. Disease commonly occurs as a recurrent vesicular eruption of the oral, perioral (typically HSV-1), or genital (typically HSV-2) regions, although primary gingivostomatitis (typically in children and young adults and caused by HSV-1) and primary genital herpes (typically HSV-2) are less common.

CLINICAL MANIFESTATIONS

Patients with primary gingivostomatitis have high fever, regional lymphadenopathy, and malaise. Patients with primary genital herpes have fever, flulike symptoms, tender inguinal adenopathy, and aseptic meningitis. These infections all reveal grouped vesicles on an erythematous base. Recurrent eruptions can be triggered by skin trauma, cold or heat, concurrent infection, and menstruation. Chronic erosive ulcers of the face and anogenital areas may develop in immunocompromised patients.

DIAGNOSIS

Tzanck smear of fluid from the roof of a vesicle can be helpful in confirming the diagnosis (see Fig. 444-15 in Chapter 444), but viral culture is the diagnostic "gold standard." The direct fluorescent antibody test is an antigen-based technique that not only yields same-day results but can also distinguish HSV from varicella-zoster virus (VZV) and is becoming widely used.

TREATMENT Rx

In healthy individuals, HSV infection is self-limited. The goal of treatment is to shorten the current attack and prevent recurrences. Acyclovir is effective in the treatment of HSV infections; valacyclovir and famciclovir are closely related, effective medications with improved oral bioavailability. The doses and duration of therapy vary depending on whether the infection is limited to the oral or genital mucous membranes or is disseminated and on whether it is primary or recurrent disease (Chapter 382).

CHICKENPOX

Chickenpox is caused by VZV (Chapter 383). It is usually a childhood disease, but affected adults have more morbidity. Skin lesions occur 10 to 21 days after exposure to VZV. Erythematous macules appear on the scalp, face, trunk, and proximal ends of the limbs, with rapid progression to papules, vesicles, pustules, and crusting (Fig. 447-15). Adults may experience a more widespread eruption, prolonged fever, and pneumonia. The diagnosis is usually made clinically, but direct fluorescent antibody or culture confirmation is sometimes needed. Treatment of healthy children is unnecessary because the disease is self-limited. Adults should be treated with oral acyclovir, 800 mg five times a day for 7 days. The varicella vaccine given once to healthy children 12 to 18 months of age and twice, in a 4- to 8-week interval, to susceptible persons older than 13 years (Chapter 17) is highly effective.

HERPES ZOSTER

PATHOBIOLOGY

Herpes zoster is caused by reactivation of VZV from a previous chickenpox infection. The disease is more common in older or immunocompromised patients.

CLINICAL MANIFESTATIONS

The typical manifestation is painful grouped herpetiform vesicles on an erythematous base confined to cutaneous surfaces innervated by one sensory nerve and preceded by radicular pain (Fig. 447-16). The major morbidity, which is pain within the affected dermatome, can be severe and persist after the skin lesions have resolved (postherpetic neuralgia). Immunocompromised patients have an increased risk for cutaneous dissemination and visceral involvement of the bladder, lungs, and CNS.

FIGURE 447-15. Erythematous macules and vesicles with crusted erosions on the chest of a patient with varicella.

FIGURE 447-16. Herpes zoster. Necrotic blisters and erosions in a dermatomal pattern are seen on the trunk of this patient.

TREATMENT Rx

Acyclovir (800 mg orally five times daily for 7 days) and its derivatives valacyclovir (500 mg orally three times daily for 7 days) and famciclovir (500 mg orally three times daily for 7 days) are safe and effective in the treatment of active disease and prevention of postherpetic neuralgia. In an immunocompromised patient, acyclovir should be given intravenously (10 mg/kg every 8 hours for 7 to 10 days). The earlier antiviral medications are started, the more effective they are in shortening the duration of herpes zoster and in preventing or decreasing the severity of postherpetic neuralgia. Oral steroids are not effective in reducing the incidence of acute pain or postherpetic neuralgia. Patients with postherpetic neuralgia of more than 3 months' duration benefit from the use of gabapentin, 1600 or 2400 mg daily, with a significant reduction in pain. ■ VZV vaccine markedly reduces both the morbidity from herpes zoster and postherpetic neuralgia in healthy adults older than 60 years. ■

PUSTULAR ERUPTIONS

Acne Vulgaris

DEFINITION

Acne vulgaris is the most common pustular skin condition. Teenagers are usually affected, but the disease may persist into adulthood. The comedo, which is the primary lesion, can be either closed (whitehead) or open (blackhead).

PATHOBIOLOGY

Androgen production after puberty stimulates the release of sebum by sebaceous glands. Sebum flow is impeded because of abnormal keratinization within the pilosebaceous canal, a process that leads to the formation of

FIGURE 447-17. Sebaceous gland hyperplasia. A large red bulbous nose known as rhinophyma is characteristic of late-stage rosacea.

FIGURE 447-18. Perioral dermatitis. Erythematous papules and pinpoint pustules are evident around the mouth.

comedones. Bacterial (*Propionibacterium acnes*) proliferation within the comedo predisposes to rupture of the pilosebaceous unit with extravasation into the surrounding dermis, which results in papules, pustules, and cysts.

TREATMENT

Rx

Patients with mild disease are treated topically with benzoyl peroxide, tretinoin, adapalene, or tazarotene, which normalize follicular keratinization. In patients with mild to moderate disease, treatment with benzoyl peroxide is the most cost-effective therapy. The addition of topical antibiotics helps control inflammatory papules and pustules. More significant disease is often treated with oral tetracycline (250 to 1000 mg/day), doxycycline (200 mg/day), or minocycline (200 mg/day). Dapsone gel (5%) is safe and effective. Another approach is oral contraceptives containing either ethinyl estradiol and norgestimate or ethinyl estradiol and drospirenone, both of which are superior to placebo in the treatment of acne in women. Isotretinoin (1 mg/kg given for 5 months), which decreases sebaceous gland size and sebum production, is reserved for severe cystic disease because of its teratogenicity, possible associated risk for depression, and other significant side effects. Acne may be exacerbated by the use of oil-based cosmetics or hair preparations. Androgenic hormones, systemic corticosteroids, lithium, phenytoin, phenobarbital, isoniazid, and endocrinologic conditions such as polycystic ovary disease and adrenal or ovarian tumors may produce acneiform eruptions or aggravate preexisting acne.

ROSACEA

Rosacea, which is a chronic inflammatory disease of the face, affects the pilosebaceous units and blood vessels and generally occurs in middle age. Erythema, telangiectases, erythematous papules, and pustules occur on the central part of the face. Ocular rosacea can lead to keratitis, iritis, blepharitis, and recurrent chalazion; it should be managed by an ophthalmologist. In its most severe form, rosacea can cause sebaceous gland hyperplasia leading to a large red bulbous nose known as rhinophyma (Fig. 447-17). Rosacea is more likely to develop in patients with a tendency toward facial flushing. Flushing can be due to heat, spicy foods, hot drinks, alcohol, or emotional stimuli. With time, the flushing reaction lasts longer and longer until it persists. Topical antibiotics, including 0.75 to 1% metronidazole, are helpful in mild disease, and the combination of a sub-antimicrobial dose (20 mg twice daily) of doxycycline plus topical 0.75% metronidazole is more efficacious than topical metronidazole alone. Patients with more severe disease require oral tetracycline, 500 mg twice daily for 3 to 4 months and then slowly decreased as tolerated. Azelaic acid gel (15%) can significantly improve papulopustular rosacea.

PERIORAL DERMATITIS

Perioral dermatitis is characterized by erythematous papules and pustules as well as scaling patches around the mouth and eyes (Fig. 447-18). Most patients have used potent topical corticosteroids inappropriately for long periods. The eruption generally clears after stopping the corticosteroid and using tetracycline, 250 mg orally twice daily for 6 weeks.

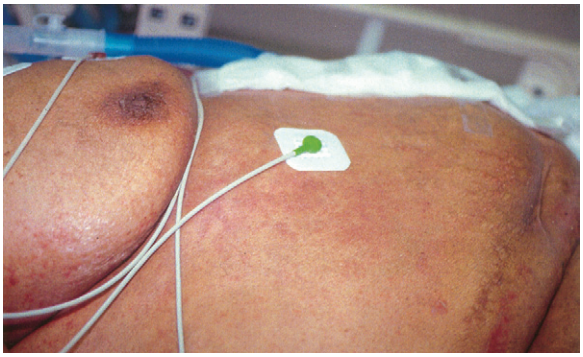

FIGURE 447-19. Acute generalized exanthematous pustulosis. Erythematous macules and numerous superficial pustules are present on the trunk of this patient.

ACUTE GENERALIZED EXANTHEMATOUS PUSTULOSIS

Acute exanthematous pustulosis is a generalized pustular eruption that is associated with fever and frequently caused by antibiotics. Pustules develop within 2 days of drug administration, start on the face or in flexural areas, and rapidly disseminate (Fig. 447-19). Spontaneous resolution occurs in less than 2 weeks.

PUSTULAR PSORIASIS

Pustular psoriasis is a variant of psoriasis (Chapter 446) that localizes to the palms and soles or generalizes over the entire body. Patients with generalized disease have fever and leukocytosis and require systemic therapy. Pustules can also be seen in patients with septic emboli of bacterial or fungal origin, including gonococcemia and systemic candidiasis (see Purpuric Eruptions).

FOLLICULITIS

Folliculitis is inflammation of the hair follicles caused by infection with staphylococci. It is due to obstruction of individual hair follicles and associated pilosebaceous units. Folliculitis is more common in patients with diabetes mellitus, obesity, or immunocompromised states. The primary lesion is a pustule with a central hair. Typical affected sites are the scalp, thighs, trunk, axilla, and inguinal area. Sometimes the infection can extend deeper into the dermis and form larger erythematous nodules from one (furuncle) or more (carbuncle) follicles. Treatment with oral antibiotics such as cephalexin, 500 mg twice daily for 14 days, clears extensive infections, whereas topical

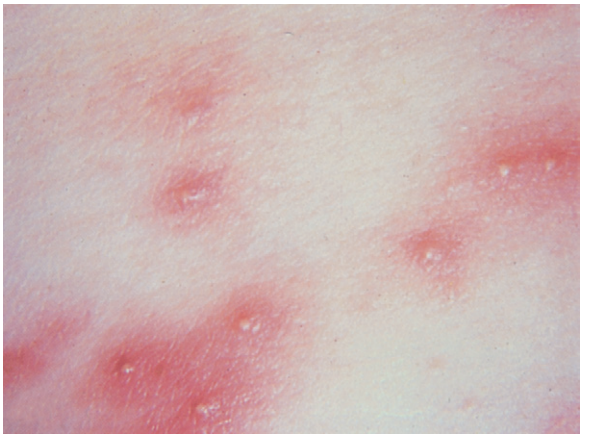

FIGURE 447-20. *Pseudomonas* species folliculitis. The trunk of this patient has numerous pustules on an erythematous base.

antibiotics (e.g., clindamycin solution applied twice daily for 2 weeks or longer) and antibacterial soaps (e.g., Dial or Lever 2000) help in milder disease.

Pseudomonas Folliculitis

Pseudomonas folliculitis is acquired from hot tubs contaminated with *P. aeruginosa* (Chapter 314). The typical finding is papules and pustules in areas of skin occluded by a bathing suit (Fig. 447-20). Treatment with ciprofloxacin, 500 mg twice daily for 10 to 14 days, is usually curative.

Pityrosporum folliculitis is a pruritic, acne-like eruption that occurs on the upper part of the back and the chest, arms, and face and is caused by *Pityrosporum ovale.* Treatment is with oral itraconazole, 200 mg/day for 1 week, and 2% ketoconazole shampoo applied to the affected area daily for 1 month.

Eosinophilic Pustular Folliculitis

Eosinophilic pustular folliculitis is a sterile, intensely pruritic folliculitis usually found on the face, chest, and back of patients who are positive for HIV (Chapter 399). Skin biopsy is needed to confirm the diagnosis. Treatment is difficult, but options include potent topical corticosteroids, such as 0.1% triamcinolone ointment applied twice daily for several months (although this class 4 topical corticosteroid should not be used on the face); tacrolimus ointment 0.1% is another topical option that is safe for facial use. Systemic options include antihistamines, such as hydroxyzine, 25 mg every 8 hours as needed, and ultraviolet light therapy.

URTICARIA, DRUG HYPERSENSITIVITY RASHES, NODULES AND TUMORS, AND ATROPHIC DISEASES

MADELEINE DUVIC

URTICARIA

DEFINITION AND EPIDEMIOLOGY

Urticaria, also known as hives, is one of the most common cutaneous reaction patterns (Fig. 448-1). It is triggered by a wide variety of antigens or by physical stimuli, including cold, pressure, and sunlight (Table 448-1). The term *urticaria* refers to a disease spectrum ranging from simple wheals to angioedema. Clinical distinction between acute and chronic urticaria is important for diagnosis and treatment. Chronic urticaria, defined as urticaria that recurs over a period of 6 weeks or more, is often of unknown cause.

Urticaria is common worldwide in persons of all ages, although certain types of urticaria have a predilection for certain age groups. For example, acute urticaria is often seen in children with atopic dermatitis, whereas chronic urticaria peaks in the fourth decade.

PATHOBIOLOGY

Urticaria can be due to immunologic (autoimmune, immunoglobulin E [IgE]-dependent, immune complex–mediated, complement-kinin dependent) or nonimmunologic (direct mast cell–releasing agents, vasoactive stimuli, drugs) reactions. Local degranulation of mast cells with the release of histamine and other factors, such as slow-reacting substance of anaphylaxis, precipitates urticaria. Functional IgG autoantibodies, which release histamine from mast cells and basophils, are commonly found in the blood of patients with chronic urticaria. Additionally, basophils are recruited into

FIGURE 448-1. Urticaria. (From www.dermnetnz.org/reactions/urticaria.html.)

TABLE 448-1 COMMON CAUSES OF URTICARIA

URTICARIA MAY BE ACCOMPANIED BY ANGIOEDEMA AND ANAPHYLAXIS
Blood products: red cells, platelets, gamma globulin
Drugs
Antibiotics: penicillins, cephalosporins, sulfonamides, isoniazid
Aspirin: salicylates, benzoates, phenylbutazone
Anticonvulsants: hydantoin
Chemotherapy: doxorubicin, daunorubicin, L-asparaginase, chlorambucil, cyclophosphamide, melphalan, methotrexate, nitrogen mustard, procarbazine
Dextran
Nonsteroidal anti-inflammatory drugs
Opiates
Quinidine
Radiocontrast dyes, iodine
Environmental: animal dander or proteins, formaldehyde, pollen, mold, plants, latex, plastic tubing, exercise, heat, cold, sunlight
Foods: berries, eggs, milk, nuts, tomatoes, shellfish, soy
Food additives: sodium benzoate, tartrazine (yellow dye #5)
Hormones
Infections: streptococcal, staphylococcal, sinusitis or abscesses, viral hepatitis, Epstein-Barr virus mononucleosis, *Candida* species
Insect bites or venom: Hymenoptera, mosquitoes, mites, scabies
Mechanical stimuli (dermographism, vibratory angioedema, delayed-pressure urticaria)
Vaccines
URTICARIA-LIKE ERUPTIONS AND REACTIVE ERYTHEMAS
Erythema multiforme: herpes simplex, DNA viruses, *Mycoplasma pneumoniae,* drugs
Erythema marginatum: streptococcal rheumatic fever
Juvenile rheumatoid arthritis
Erythema chronicum migrans: *Borrelia* species infections
Erythema annulare centrifugum: tinea, drugs
Figurate erythemas: erythema repens (often with underlying carcinoma)
Urticaria pigmentosa (mastocytosis)

the wheals, where they sustain the response by releasing histamine. Eosinophils also contribute through leukotriene C_4 (LTC_4), leukotriene D_4 (LTD_4), leukotriene E_4 (LTE_4), and major basic protein. Urticaria is typically transient and self-limited, without leakage of blood cells into the skin or damage to the blood vessels. Leakage of plasma into the dermis from capillaries and small postcapillary venules correlates clinically with development of a demarcated, pink, raised lesion (hive).

CLINICAL MANIFESTATIONS

Urticarial lesions are pink to light red, blanch with pressure, and are raised above the surface of the skin. The center of the lesions may be paler than the leading edge. By definition, individual wheals come and go within 24 hours. A mosquito bite (Chapter 261) is the archetypal urticarial lesion. Individual hives can coalesce into giant plaques or annular rings called giant urticaria as is seen in serum sickness, in which they are accompanied by arthralgias and fever. Confluent urticaria may also be accompanied by swelling of the underlying soft tissue or the mucous membranes (angioedema) as well as by anaphylaxis with laryngeal edema, a life-threatening emergency. In otherwise normal individuals, pressure or writing on the skin will cause spontaneous local release of histamine, which induces a wheal-and-flare reaction known as dermatographism. Deep swelling develops at the site of sustained pressure and may remain for days in a condition known as delayed pressure urticaria. Affected individuals may develop lesions from tight-fitting clothing, shoes, socks, or sexual intercourse.

Other physical stimuli such as cold, heat, sun, or exercise may induce urticaria. Cold urticaria may be precipitated by putting an ice cube on the skin; the interval until hives develop and the duration of the hives correlate with the severity of the condition, which can be life-threatening if the patient is suddenly immersed in cold water. Heat, exercise, or exertion may be accompanied by small, 2- to 3-mm urticarial lesions in a condition called cholinergic urticaria. Exercise-induced anaphylaxis may be hereditary, but the defect is unknown. Patients with vibratory angioedema develop swelling and erythema within a few minutes of exposure to a vibratory stimulus. Lesions persist for about 30 minutes. Other forms of physically induced urticaria include solar urticaria and aquagenic urticaria (urticarial lesions caused by exposure to sun and water, respectively).

FIGURE 448-2. Erythema marginatum. (From www.medscape.com/content/1998/00/41/73/417394/art-m5649.fig2.jpg.)

Food-and-exercise-induced anaphylaxis is a syndrome in which a few minutes of exercise following ingestion of certain specific foods results in angioedema or anaphylaxis. The cause of this syndrome is unknown.

DIAGNOSIS

A detailed history (duration, occupation, medications, frequency of episodes, associated illness) is critical. Urticaria typically results from exposure to antigen only minutes to a few hours before onset of the lesions. In many cases, pruritus may precede onset of the rash. The most common triggers of IgE-mediated allergic urticarial reactions are drugs (especially penicillin, sulfa drugs, antibiotics, and contrast dye), foods (shellfish, salicylates in berries, tomatoes, yeast, and penicillin in blue cheese), food additives (sodium benzoate), nuts (especially peanuts), or insect bites. Nonimmunologic mediators of urticaria include aspirin and opiates as well as physical agents that work through the prostaglandin pathway or degranulate mast cells.

Acute urticaria can also be triggered by skin contact with an antigen, such as latex, and can progress to anaphylaxis. In addition, urticaria can be a sign or prodrome of a latent infection, especially streptococcal pharyngitis in children or viral hepatitis in adults. The migratory urticarial rash accompanying rheumatic fever, erythema marginatum (Fig. 448-2), is characterized by evanescent, scalloped lesions that change location over the course of hours.

When urticarial lesions are present for more than 24 hours, underlying urticarial vasculitis should be suspected. A skin biopsy is required to distinguish urticarial vasculitis from urticaria in which no damage to the blood vessels is evident. When vascular damage is present, the lesion is termed *leukocytoclastic vasculitis,* the most severe expression of hypersensitivity reactions involving cutaneous blood vessels.

Chronic urticaria can be caused by occult infections (sinusitis, gallbladder disease, *Helicobacter pylori,* yeast infections, tooth abscesses, or silent hepatitis) as well as by collagen vascular diseases and tumors, especially Hodgkin's lymphoma. Deficiency of the C1 esterase inhibitor can be manifested as chronic urticaria with angioedema. Allergy testing is recommended if the history is unrevealing. If lesions persist for more than 24 hours, skin biopsy is indicated to determine whether vasculitis or mastocytosis is present. If infection, collagen vascular disease, or a tumor is suspected, a full serologic evaluation should be undertaken. Although a thorough medical evaluation may aid in diagnosis, the cause of chronic urticaria may remain uncertain. In the absence of a known antigen, stress is often invoked as the underlying cause of chronic recurrent idiopathic urticaria.

Systemic mastocytosis (Chapter 263) may be accompanied by urticarial lesions and gastrointestinal symptoms. In the form of mastocytosis known as *urticaria pigmentosa,* stroking the lesions produces urticaria, known as *Darier's sign.* A skin biopsy shows an increased number of dermal mast cells. Serum tryptase and histamine levels may be elevated during an attack.

TREATMENT Rx

Management of urticaria depends on its severity and the duration of the problem (Chapter 260). For mild urticaria limited to the skin, traditional antihistamines (diphenhydramine) or the newer nonsedating agents (terfenadine, cetirizine, loratadine)[T] can be administered by mouth intermittently as needed (Table 448-2). Acute urticaria is often treated with diphenhydramine orally. If the urticaria is severe, short-term corticosteroids, up to 1 mg/kg, can be used. For urticaria associated with wheezing or anaphylaxis, subcutaneous

epinephrine, intravenous corticosteroids, and oxygen should be administered immediately. For chronic urticaria despite antihistamines, cyclosporine at doses of 3 mg/kg or higher for 8 to 16 weeks may be helpful. ■ Finding the cause and removing the antigen of chronic recurrent urticaria is highly preferable to chronic administration of corticosteroids or antihistamines. The patient should avoid aspirin compounds and other drugs that could be the cause.

DRUG RASHES

DEFINITION

Drugs have been associated with every type of cutaneous reaction pattern ranging from mild and self-limited to severe and life-threatening. Urticaria and exanthematous eruptions are common manifestations of cutaneous drug reactions. Less commonly seen are fixed drug, lichenoid, pustular, phototoxic, bullous, or vasculitic reactions, as well as Stevens-Johnson syndrome and toxic epidermal necrolysis.

PATHOBIOLOGY

Drug rashes, which result from drug toxicity, overdose, drug-drug interactions, or products of metabolism, may be caused by immunologic or nonimmunologic mechanisms. Drugs or their metabolites can act as haptens and induce cell-mediated or humoral responses. Mechanisms include IgE-dependent anaphylaxis and urticaria, cytotoxic reactions resulting in thrombocytopenia and resultant petechiae, immune complex–mediated serum sickness, and delayed-type hypersensitivity resulting in exanthematous or fixed drug eruptions or Stevens-Johnson syndrome.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most drug rashes are either immediate (urticaria) or delayed hypersensitivity reactions (exanthems). Immediate reactions such as pruritus, hives, angioedema, and anaphylaxis occur within minutes to a few hours after the drug is taken. The most common drug-related rash (Table 448-3) is a T-cell–mediated hypersensitivity reaction manifested as a macular, bright pink to salmon-colored exanthem that appears as early as 7 to 10 days and as late as 14 days after a drug is first administered. Delayed hypersensitivity reactions can be macular or papular exanthems (or both), morbilliform eruptions, annular erythema, or confluent erythema (Fig. 448-3). Once sensitization to a particular drug has occurred, readministration of the same drug may trigger an eruption within 24 to 72 hours. Drug hypersensitivity reactions are typically symmetrical. They characteristically begin on the face and upper trunk and progress to the lower extremities, where they may become purpuric. Exanthems secondary to drugs most often become confluent erythematous patches after several days.

TABLE 448-2 TREATMENT OF URTICARIA

1. Avoid the inciting agent!
2. Medications based on severity
   - A. Mild to moderate, acute urticaria
     Oral antihistamines, e.g., diphenhydramine (Benadryl), 10-50 mg PO q12h, or hydroxyzine, 10-25 mg PO q8h; nonsedating alternatives include cetirizine (Zyrtec), 5-10 mg, or loratadine (Claritin), 10 mg/day
   - B. Severe urticaria with or without angioedema
     Antihistamines, e.g., diphenhydramine (Benadryl), 25-50 mg PO q6-8h or 10-50 mg IV q2-4h, not to exceed 400 mg/24 hr
     Corticosteroids, e.g., prednisone, 10-60 mg PO every morning with tapering over a 2-wk period, triamcinolone (Kenalog), 40 mg IM for one dose, or dexamethasone, 0.6-0.75 mg/m^2/day IV in divided doses q6-12h, depending on severity
   - C. Anaphylaxis
     A—Airway (intubation)
     B—Breathing (oxygen)
     C—Circulation: parenteral aqueous epinephrine, 1:1000 IV, saline or volume expanders
     IV corticosteroids (e.g., methylprednisolone, 125 mg)
     Histamine H_1- and H_2-antagonists (50 mg each of diphenhydramine and ranitidine)
   - D. Chronic idiopathic urticaria—combination therapy
     Nonsedating antihistamine: cetirizine, 10 mg/day, or fexofenadine, 30-180 mg twice daily, alone or with montelukast, 10 mg/day, or H_1- and H_2-antagonists (50 mg each of diphenhydramine and ranitidine) and/or low-dose corticosteroids (if unavoidable)

Pruritus is the most common symptom. The differential diagnosis for drug rashes includes viral exanthems (Chapter 447), graft-versus-host disease or the leukocyte recovery rash after allogeneic bone marrow transplantation, erythematous exanthems that accompany streptococcal [scarlet fever (Chapter 298)] or staphylococcal [toxic shock syndrome (Chapter 296)] infections, and the acute manifestation of collagen vascular diseases. A similar exanthem occurs when ampicillin is administered to patients who have infectious mononucleosis. A careful drug history is critical in diagnosis and treatment.

TREATMENT AND PROGNOSIS

Rx

After the offending drug is discontinued, delayed hypersensitivity reactions resolve in about a week. Therapy is mostly supportive. Corticosteroids, such as 0.01% triamcinolone cream applied several times per day to the affected area, and antihistamines given orally three to four times daily are helpful in reducing the itching and shortening the course.

Specific Syndromes

DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS

An especially severe hypersensitivity *drug rash with eosinophilia and systemic symptoms* (DRESS) is most frequently seen with sulfonamides and anticonvulsants (Fig. 448-4). This condition is thought to be due to an alteration in drug metabolism. Activated T lymphocytes release interleukin-5 (IL-5),

TABLE 448-3 DELAYED HYPERSENSITIVITY DRUG RASHES BY CATEGORY

MACULOPAPULAR EXANTHEMS—ANY DRUG CAN PRODUCE A RASH 7-10 DAYS AFTER THE FIRST DOSE
Allopurinol Antibiotics: penicillin, sulfonamides Antiepileptics: phenytoin, phenobarbital Antihypertensives: captopril, thiazide diuretics Contrast dye: iodine Gold salts Hypoglycemic drugs Meprobamate Phenothiazines Quinine
DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS (DRESS)
Anticonvulsants: phenytoin, phenobarbital, valproate, lamotrigine Antibiotics: sulfonamides, minocycline, dapsone Allopurinol Phenothiazines
ERYTHEMA MULTIFORME/STEVENS-JOHNSON SYNDROME
Sulfonamides, phenytoin, barbiturates, carbamazepine, allopurinol, amikacin, phenothiazines Toxic epidermal necrolysis: same as for erythema multiforme but also acetazolamide, gold, nitrofurantoin, pentazocine, tetracycline, quinidine
ACUTE GENERALIZED EXANTHEMIC PUSTULOSIS
Antibiotics: penicillins, macrolides, cephalosporins, clindamycin, imipenem, fluoroquinolones, isoniazid, vancomycin, minocycline, doxycycline, linezolid Antimalarials: chloroquine, hydroxychloroquine Antifungals: terbinafine, nystatin Anticonvulsants: carbamazepine Calcium-channel blockers Furosemide Systemic corticosteroids Protease inhibitors
COLLAGEN VASCULAR OR LUPUS-LIKE REACTIONS
Procainamide, hydralazine, phenytoin, penicillamine, trimethadione, methyldopa, carbamazepine, griseofulvin, nalidixic acid, oral contraceptives, propranolol
ERYTHEMA NODOSUM
Oral contraceptives, penicillin, sulfonamides, diuretics, gold, clonidine, propranolol, opiates Fixed drug reactions: phenolphthalein, barbiturates, gold, sulfonamides, meprobamate, penicillin, tetracycline, analgesics

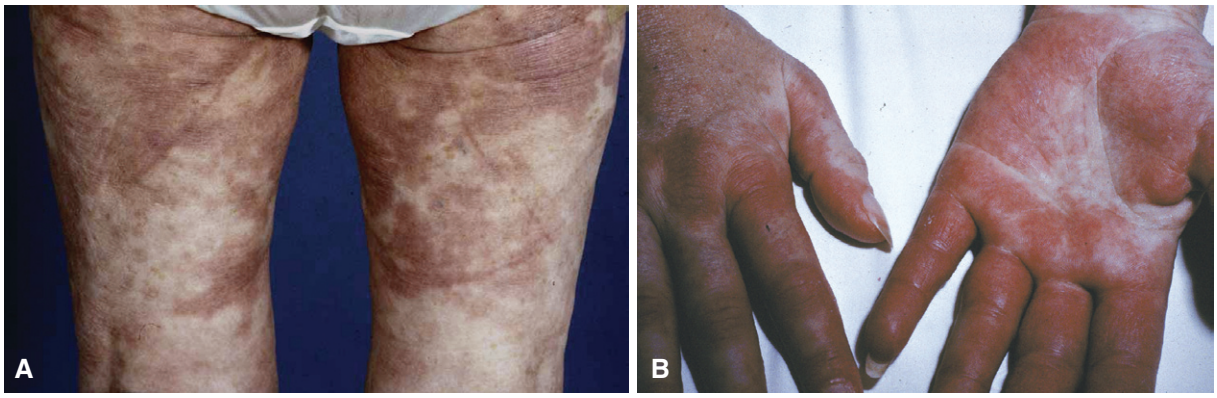

FIGURE 448-3. **Delayed hypersensitivity reaction. A,** Drug reaction. **B,** Acral erythema.

FIGURE 448-4. **Hypersensitivity drug rash caused by phenytoin.**

leading to characteristic eosinophilia. DRESS may be delayed in onset by 2 to 6 weeks, persists longer than classic drug-induced eruptions, and becomes generalized and severe, even when use of the agent is discontinued. It typically begins as a morbilliform eruption, which later evolves into an edematous pustular eruption with erythroderma and purpura. The rash begins on the face, upper trunk, and extremities and later becomes generalized. Continued administration of the drug can result in exfoliative erythroderma, toxic necrolysis, and systemic hypersensitivity, including hepatitis (50%), nephritis (10%), or atypical lymphocytosis and lymphadenopathy mimicking mononucleosis or T-cell lymphoma. Less commonly seen are pneumonitis, myocarditis, and pericarditis. With visceral involvement, there is a 10% mortality rate, usually from hepatic failure. This condition is thought to be due to an alteration in drug metabolism. Activated T lymphocytes release IL-5, leading to characteristic eosinophilia.

ERYTHEMA MULTIFORME, STEVENS-JOHNSON SYNDROME, AND TOXIC EPIDERMAL NECROLYSIS

Stevens-Johnson syndrome and toxic epidermal necrolysis represent a spectrum of the same disease, of which erythema multiforme (see Fig. 447-10 in Chapter 447) is the least severe. Stevens-Johnson syndrome is defined as less than 10% body surface area involvement, and toxic epidermal necrolysis is defined as greater than 30% body surface area involvement. Erythema multiforme, a hybrid of urticaria and vasculitis, consists of symmetrically distributed red macules or papules that evolve into classic target or bull's eye lesions with deep red centers and pink urticarial rims. It is commonly precipitated by herpes simplex infections, other DNA viruses, or drugs. Stevens-Johnson syndrome is characterized by severe mucosal involvement with purpuric lesions. Widespread epidermal necrosis is seen in toxic epidermal necrolysis. Drugs are almost always implicated when Stevens-Johnson syndrome or toxic epidermal necrolysis develops in adults (Fig. 448-5). Commonly implicated medications include nonsteroidal anti-inflammatory drugs (NSAIDs), allopurinol, phenytoin, and sulfa drugs. Alterations in drug metabolism (i.e., slow acetylators of sulfonamides) are often implicated. Extensive keratinocyte necrosis leads to separation at the dermal-epidermal junction. Symptoms include fever, severe pain, or sometimes asthenia. The condition can progress rapidly, so it is critical to determine and discontinue the causative agent immediately. Superinfection and fluid and electrolyte imbalances can lead to death in 5% of cases of Stevens-Johnson syndrome and 30% of cases of toxic epidermal necrolysis.

LEUKOCYTOCLASTIC VASCULITIS

Severe drug reactions can also be manifested as vasculitis, neutrophilic eruptions, and ulcerations. Vasculitis is further categorized by the size of the involved vessel and the nature of the cellular reaction and immune complexes. Leukocytoclastic vasculitis, which is the most common form of vasculitis induced by drugs, is manifested as palpable purpura, usually on the extremities (see Figs. 447-4 and 447-5 in Chapter 447).

NEUTROPHILIC DRUG REACTIONS

Neutrophilic drug reactions include iododermas, bromodermas, and Sweet's syndrome (acute febrile neutrophilic dermatosis. Acute generalized exanthematous pustulosis is characterized by numerous (>100), small (<5 mm), nonfollicular subcorneal pustules that arise on erythematous skin, often beginning in skin creases or on the face. High fever and peripheral neutrophilia may precede or accompany the eruption. The pustules are sterile, present for 5 to 10 days, and followed by desquamation. They usually appear less than 2 days after the administration of the causative drug. Ninety percent of cases are due to drugs, most commonly β-lactam antibiotics, macrolides, and calcium-channel blockers. This syndrome has also been called pustular drug rash, pustular psoriasis after corticosteroid withdrawal, and toxic pustuloderma. When severe, it may be confused with toxic epidermal necrolysis, but the mortality rate is only 1 to 2%. Skin patch testing is frequently positive.

FIXED DRUG ERUPTIONS

A fixed drug reaction appears at the same location 1 to 2 weeks after first drug exposure and within 24 hours of repeat exposure. The lips, hands, face, feet, and genitalia are most commonly involved. The lesion may begin as erythema and then become gray, brown, or violaceous. Trimethoprim-sulfamethoxazole, NSAIDs, tetracyclines, and pseudoephedrine are common causes. Epidermal growth factor receptor inhibitors and protein kinase inhibitors cause an acneiform eruption on the face and chest that is associated with drug response (Fig. 448-6).

PHOTOSENSITIVITY AND WITHDRAWAL REACTIONS

Light combined with drugs (Table 448-4) can produce photosensitivity reactions that can be quite severe and mimic sunburn. Ultraviolet radiation interacts with a drug or its metabolite to generate reactive oxygen species, leading to cellular damage. Tetracyclines, sulfa drugs, NSAIDs, and fluoroquinolones are often implicated in photosensitivity reactions. Photosensitizing drugs may exacerbate lupus erythematosus (Chapter 274) or porphyria cutanea tarda (Chapter 217).

CONTACT DERMATITIS

Allergic contact dermatitis is a T-cell–mediated delayed hypersensitivity reaction following topical drug application or exposure to poison ivy, oak, or sumac. It is manifested by erythema and microvesiculation and may spread beyond the area of application (id reaction). Common contact sensitizers include Neosporin (polymyxin B/neomycin/bacitracin), bacitracin, diphenhydramine, doxepin, lidocaine, lanolin, mercury, and *p*-aminobenzoic acid.

BENIGN PAPULES, NODULES, AND TUMORS

The skin is heterogeneous, composed of epidermis, dermis, subcutaneous compartments, and blood vessels. The skin hosts a number of migrating cells (Chapter 443), all of which can give rise to benign or malignant tumors. Lesions that arise from epidermal keratinocytes are usually papules (warts, sebaceous hyperplasia) or plaques (psoriasis, Bowen's disease). Nodules are deeper lesions that may be tender or asymptomatic, single or multiple, and break down to form ulcers. Nodules are classified as inflammatory (granulomas, vasculitis, or panniculitis), infectious, vascular, or metabolic; they can be benign or malignant tumors that arise from skin cells or migrant cells (Table 448-5). Nodules that are smaller and symmetrical are more likely to

TABLE 448-5 TUMORS AND NODULES OF THE SKIN

Benign, nonpigmented tumors and nodules
Epidermal: warts, acrochordons, tricholemmomas, sebaceous hyperplasia
Adnexal: epidermal cysts, syringomas, follicular cysts, pilomatricoma, apocrine or eccrine adenomas
Dermal and subcutaneous: lipomas, angiolipomas, neurofibromas, leiomyomas
Benign, pigmented tumors and nodules
Epidermal: seborrheic keratoses
Melanocytic compound nevi (junctional nevi are flat)
Spitz nevus
Blue nevus
Dermatofibromas
Malignant, nonpigmented tumors and nodules
Basal cell carcinoma (nodular, superficial, morpheaform, pigmented)
Squamous cell carcinoma (actinic keratoses, Bowen's disease, keratoacanthomas)
Cutaneous T- and B-cell lymphomas
Amelanotic melanomas
Merkel cell carcinomas
Adnexal carcinomas of the sebaceous and apocrine glands
Malignant, pigmented tumors and nodules
Pigmented basal cell carcinoma
Malignant melanoma: in situ, superficial spreading, nodular, acral lentiginous
Dermatofibrosarcoma protuberans
Inflammatory nodules over joints
Gottron's papules (dermatomyositis)
Gouty tophi
Heberden's nodes (osteoarthritis)
Multicentric reticulohistiocytosis (paraneoplastic syndrome)
Rheumatoid nodules
Granuloma annulare
Inflammatory nodules of the lower extremities
Panniculitis
Vasculitis: periarteritis nodosa
Metabolic nodules of the skin
Amyloidosis
Gouty tophi
Xanthomas, necrobiotic xanthogranuloma
Xanthelasma
Vascular lesions
Benign: nevus flammeus, angiokeratomas, spider hemangiomas, capillary hemangiomas, cavernous hemangiomas, blue rubber bleb nevi, pyogenic granulomas
Malignant: Kaposi's sarcoma, angiosarcoma

FIGURE 448-7. Actinic keratoses.

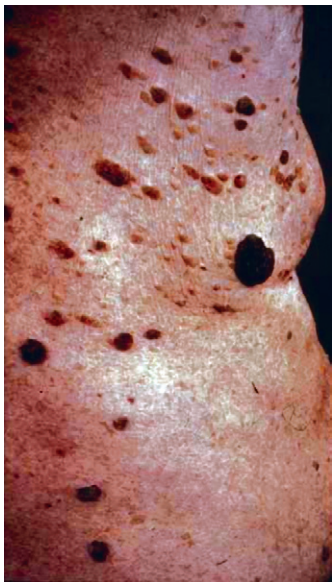

FIGURE 448-8. Seborrheic keratoses.

be benign than lesions that grow rapidly, are larger, or invade surrounding tissue. Any rapidly changing skin nodule should be investigated with an excisional biopsy to the level of fat and sent for histology as well as for bacterial, fungal, and acid-fast cultures.

Benign Epidermal Tumors

The top layer of skin is the avascular epidermis composed of keratinocytes that undergo apoptosis to form the stratum corneum. Melanocytes, Langerhans cells, and inflammatory cells may enter the epidermis. Epidermal stem cells form adnexal organs such as hair follicles and sebaceous, eccrine, and apocrine glands that can give rise to tumors.

ACTINIC KERATOSES

Actinic keratoses are pink, scaly macules composed of sun-damaged keratinocytes and are precursors of in situ squamous cell carcinoma (Bowen's disease) or invasive squamous carcinomas (Chapter 210). Actinic keratoses are 0.1 to 1.0 cm and are found on sun-exposed areas such as the forearms, hands, face, and scalp (Fig. 448-7). Lesions with induration, thick crusts, ulceration, or pain are excised for biopsy to exclude invasive squamous cell carcinoma. Actinic keratoses are treated with cryotherapy and topical fluorouracil, retinoids, or imiquimod. To treat and prevent actinic keratoses, sun-exposed areas may be treated topically with 5-fluorouracil cream (5%) applied daily for 2 weeks or twice weekly for 8 weeks.

SEBORRHEIC KERATOSES

Seborrheic keratoses are common verrucous or stuck-on epidermal papules of various colors (Fig. 448-8). They are commonly seen with advancing age

FIGURE 448-9. Molluscum contagiosum in an immunocompromised patient.

but may arise suddenly (sign of Leser-Trélat) in association with internal malignancy. Seborrheic keratoses are composed from a single clone of keratinocytes and inherited as an autosomal dominant trait. Their surface may be friable, and lesions can be scraped off. Seborrheic keratoses spare the palms, soles, and mucosal surfaces. Although benign, seborrheic keratoses must be differentiated from melanocytic nevi, melanomas, and pigmented basal cell carcinoma, usually by the presence of white to yellow horn cysts on their surface, best appreciated with dermoscopy.

WARTY LESIONS

Epidermal papules include common warts (see Fig. 447-2 in Chapter 447) caused by human papillomavirus (HPV). HPV can also be detected in squamous carcinomas arising on the digits and in keratoacanthomas, which are low-grade, well-demarcated, dome-shaped papules or nodules that grow rapidly and spontaneously involute in 6 to 8 weeks. Acrodermatitis verruciformis is characterized by multiple warts with the appearance of seborrheic keratoses on the dorsal extremities and gives rise to squamous cell carcinomas. Molluscum contagiosum (Chapter 447) (Fig. 448-9), caused by a DNA virus, are small, shiny, domed-shaped, 1- to 5-mm papules with a central dell. They are common in children and immunocompromised patients.

Cowden's syndrome (Chapter 199), caused by mutations in *PTEN* gene, is associated with warty papules (tricholemmomas; Fig. 448-10), cobblestone papules on the gums and tongue, fibrous papules, and multiple hamartomas involving the breast, thyroid, intestines, ovary, and cerebellum.

ADNEXAL TUMORS

Adnexal tumors arise from hair follicles or glands and are commonly found on the face or scalp. Trichoepitheliomas resemble basal cell carcinomas. Sebaceous hyperplasia consists of small yellow papules with a central depression. Adnexal tumors of sebaceous origin, including sebaceous adenomas and sebaceous carcinomas, also found on the face, can be markers for the Muir-Torre syndrome of familial breast and colon cancer. Epidermal or sebaceous cysts, which are found in acne or as single firm nodules with a central pore, are filled with sebum or keratin. Epidermoid tumors of the scalp and a family history of colon cancer raises question of a diagnosis of Gardner's syndrome (Chapter 199).

DERMATOFIBROMAS AND COLLAGENOMAS

Fibroblasts, the resident cells of the dermis, produce collagen, elastin, and mucopolysaccharides. Accumulation of these products results in sclerosis, papules, or nodules. Fibroblasts in small dense clusters form firm brown or tan papules known as dermatofibromas. Dermatofibromas are commonly found on the extremities and may form after insect bites or trauma. They are firm and well-demarcated papules, and the skin puckers when lateral pressure is applied. Dermatofibromas can be treated, but increased scarring may occur. The malignant counterpart is dermatofibroma sarcoma protuberans, which is a poorly defined, rapidly expanding, dermal, malignant tumor. Overlying erythema or hyperpigmentation is often present.

Collagenomas and elastic tumors with the appearance of small white to yellow papules are found in the skin and bone of patients with Buschke-Ollendorff syndrome. *Pseudoxanthoma elasticum* (Chapter 268), an autosomal recessive disorder, is typically manifested as cutaneous yellow plaques on the neck or antecubital fossa from damaged elastin tissue. Mucin cysts are gray, shiny, well-demarcated, round nodules that generally arise on the

FIGURE 448-10. Cowden's syndrome: cobblestone gums *(left)* and tricholemmoma *(right)*.

FIGURE 448-11. Neurofibromatosis with cafe au lait spots and neurofibromas.

FIGURE 448-12. Schwannoma.

mucosa or on the digits, where they may have an underlying connection to the joint space.

NEURAL CREST CELL TUMORS

Benign tumors in the dermis arising from neural crest cells include neurofibromas (soft, flesh-colored papules; Fig. 448-11), schwannomas (larger subcutaneous soft tumors or plaques; Fig. 448-12), and melanocytic lesions. Although solitary neurofibromas may occur, multiple lesions with cafe au lait spots (tan macules) or axillary freckling (Crowe's sign) are diagnostic of neurofibromatosis type I, an autosomal dominant disorder caused by mutations in neurofibromin (Chapter 426). Schwannomas can become malignant and be manifested as dermal nodules. Merkel cell carcinoma, which is a neuroendocrine carcinoma of the skin, is a particularly aggressive small cell tumor arising from the cutaneous nerve endings or Meissner's corpuscles. Merkel cell polyomavirus is associated with development of Merkel cell carcinoma. Merkel cell carcinoma may present as a solitary pink to purple dome-shaped papule on the head or neck (Fig. 448-13). Treatment requires full excision, radiation therapy, and often chemotherapy because the cancer tends to recur and metastasize.

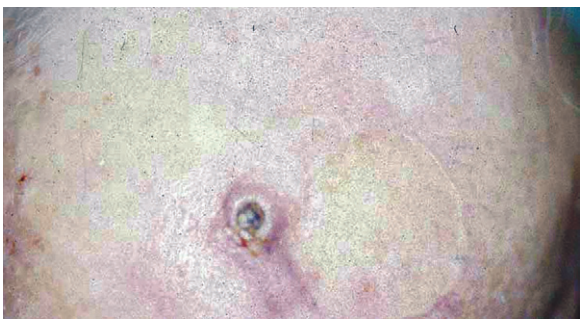

FIGURE 448-13. Merkel cell tumor.

Melanocytic Lesions

Benign melanocytic moles or nevi (new) are discrete nests of melanocytes acquired during childhood and young adulthood, stimulated by sun exposure. Nevi are benign and composed of melanocytes (Chapter 210). They regress with age and change in color during pregnancy. Benign melanocytic nevi are formed by nests of melanocytes at the epidermal junction (junctional nevi), in the dermis (intradermal nevi), or in both compartments (compound nevi). Their appearance depends on type and age of the lesion. Junctional nevi (Fig. 448-14) are small, flat, and light to dark brown. Intradermal nevi are soft, flesh-colored to pink papules with smooth regular borders and surface. Compound nevi are papules with pigmentation. Blue nevi (Fig. 448-15) are flat, grayish blue, and regular. Small congenital nevi are dark brown, whereas dysplastic nevi (Fig. 448-16) have variegated colors and may transform into melanoma. More than 10 large, atypical moles with irregular borders and colors confer higher risk of developing melanoma, especially with a positive family history. Other recognized risk factors for melanoma include having more than 50 small nevi, red or blonde hair, or fair skin that burns and a history of blistering sunburns as a child. Patients with higher risk for melanoma should have surveillance and regular skin examinations.

Langerhans Cell Histiocytosis

Skin surveillance is mediated by antigen-presenting cells: Langerhans cells, dermal dendritic cells, and skin-homing T lymphocytes. Proliferation of

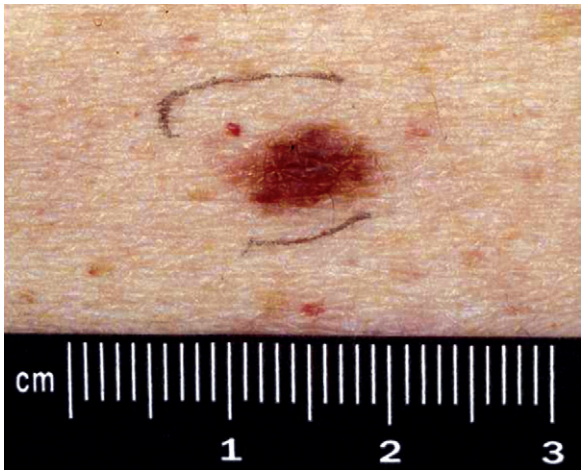

FIGURE 448-14. Junctional nevus.

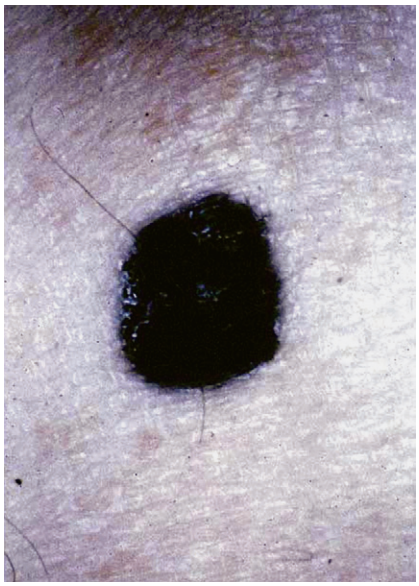

FIGURE 448-15. Benign blue nevus.

FIGURE 448-16. Dysplastic nevus syndrome.

Langerhans cells is called histiocytosis. Childhood histiocytosis X is manifested as severe seborrheic dermatitis of the scalp and gluteal areas with underlying purpura and may result in the hemophagocytic syndrome. In adults, lesions appear in the intertriginous areas (Fig. 448-17). Patients with the non–Langerhans cell histiocytosis have lytic bone involvement

FIGURE 448-17. Histiocytosis X.

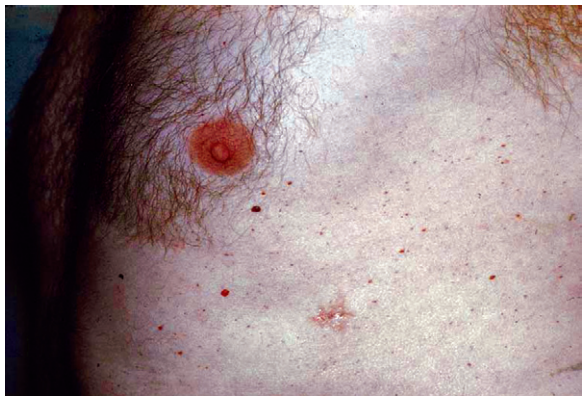

FIGURE 448-18. Benign capillary hemangioma.

(eosinophilic granulomas) or diabetes insipidus (Hand-Schüller-Christian syndrome).

Vascular Lesions

HEMANGIOMAS

Benign capillary, or cherry, hemangiomas are bright cherry-red to purple papules, generally less than 5 mm in diameter. They appear on the trunk with aging and may be numerous (Fig. 448-18). Pyogenic granulomas can resemble hemangiomas but contain polymorphonuclear leukocytes, are friable, and bleed easily. Multiple pyogenic granulomas are seen in infectious bacillary angiomatosis in immunocompromised hosts (Chapter 323). Cavernous or strawberry hemangiomas can also appear in the neonatal period as rapidly growing vascular tumors; they may obstruct the eye or the pharynx before regressing. Corticosteroids, interferon, or antiangiogenic factors can be used to treat these lesions successfully. Cavernous hemangiomas are deeper and less likely to resolve than smaller lesions. When associated with platelet consumption, the Kasabach-Merritt syndrome is present (Chapter 174).

KAPOSI'S SARCOMA

Kaposi's sarcoma (Chapter 399) is a disseminated angiomatosis that arises from viral IL-8 production by herpesvirus 8. Lesions are symmetrical purple, red, gray, or brown patches, papules, nodules, or ulcers (Fig. 448-19). Mucosal involvement is more common in advanced disease. Kaposi's sarcoma in young African adults and Kaposi's sarcoma associated with human immunodeficiency virus (HIV) infection often have a more aggressive course than Kaposi's sarcoma in elderly men of Mediterranean background, whose disease is indolent and often confined to the lower extremities. Treatment of HIV disease with highly active antiretroviral therapy has been associated with a marked decreased incidence and severity of HIV-associated Kaposi's sarcoma. Angiosarcomas are malignant purple to red vascular tumor nodules that are more common in elderly individuals or on the extremities of patients with chronic lymphedema.

Inflammatory and Hematopoietic Papules and Tumors

Inflammatory diseases of the skin involve the superficial or dermal vessels or subcutaneous tissue. Inflammatory infiltrates can be mixed or restricted in

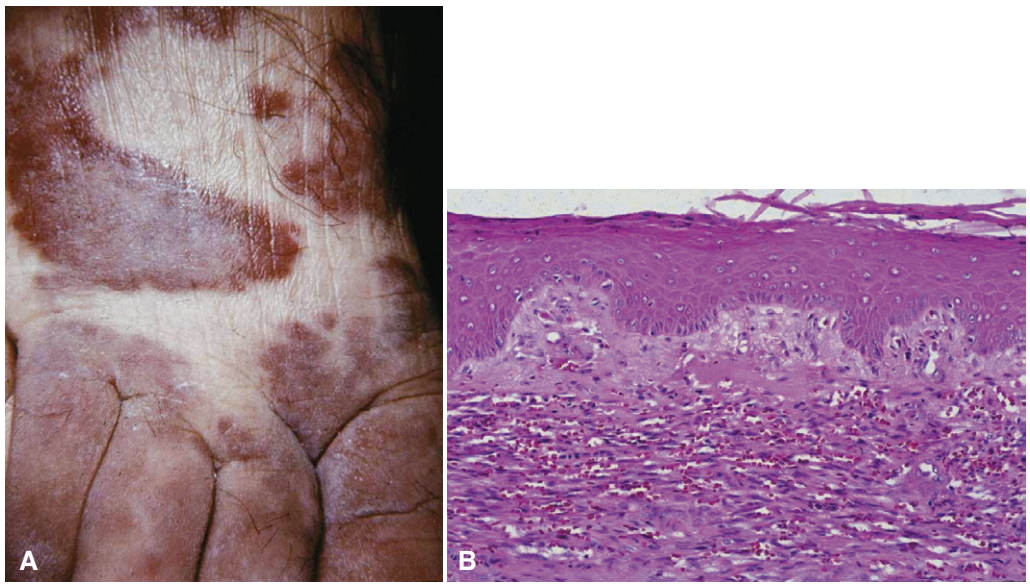

FIGURE 448-19. Kaposi's sarcoma. A, Involvement of the lower extremity (Mediterranean Kaposi's sarcoma). **B,** Histology.

FIGURE 448-20. Cutaneous sarcoidosis.

FIGURE 448-21. Leonine facies associated with lepromatous leprosy.

nature. Lymphocytes, polymorphonuclear leukocytes, histocytes, eosinophils, and plasma cells are the most common inflammatory reactions. Hematologic malignancies can present with secondary skin lesions, including patches, nodules, papules, or vasculitic lesions. Skin-homing $CD4^+$ T cells give rise to cutaneous T-cell lymphomas. Mycosis fungoides (Chapter 191) lesions are pleomorphic pink, white, or brown patches or plaques, alopecia, or diffuse erythroderma with blood involvement (Sézary's syndrome). Early patch or plaque mycosis fungoides is indistinguishable from chronic eczematous or psoriasiform dermatitis. Tumors occur late in mycosis fungoides and can transform to a large cell lymphoma phenotype, with or without expression of CD30. Peripheral cutaneous T-cell lymphomas may also be found in subcutaneous tissue as panniculitic lesions. Lymphomatoid papulosis is characterized by crops of red to pink self-regressing papules with a histology similar to anaplastic large cell lymphoma, including expression of CD30 antigen. Lymphomatoid papulosis, $CD3^+$ anaplastic T-cell lymphoma, and transformed $CD30^+$ mycosis fungoides should be distinguished for treatment. Natural killer T-cell lymphomas, immunoblastic lymphomas, and plasmacytoid dendritic cell tumors appear as brown to purple dermal nodules.

Cutaneous B-cell lymphomas present as pink, infiltrated, dome-shaped shiny papules or tumors. Follicular B-cell lymphoma is commonly located on the face, scalp, or upper part of the back, whereas mucosa-associated B-cell tumors are more common on the trunk. With the exception of large cell lymphoma, many B-cell lymphomas of the skin are indolent, and some are stimulated by *Borrelia* species infection (Chapter 329) or chronic inflammation. Plasmacytomas can arise in the skin, in bone, with multiple myeloma (Chapter 193), or independently. Extramedullary hematopoiesis or endometriosis can be associated with red or brown nodules in the dermis.

Granulomatous Diseases

Sarcoidosis is an inflammatory granulomatous process manifested as ichthyosis, papules, plaques, or tumors with an apple-jelly color (Fig. 448-20). Patients with lepromatous leprosy also can have histiocytic plaques or tumors (Fig. 448-21); treatment of leprosy may induce an inflammatory reaction called erythema nodosum leprosum. Granulomatous inflammation within the dermis can result in damage to collagen, as seen in granuloma annulare (ringlike pink to red infiltrated lesions, often on the hands or elbows), rheumatoid nodules that occur on the extensor surface of the arms, and necrobiosis lipoidica on the shins of diabetic patients. All three lesions typically include fibrin deposits within dermal blood vessels. Multicentric reticulohistiocytosis is a rare paraneoplastic syndrome in which histiocytic nodules form over joints with associated arthritis.

Inflammatory Skin Nodules

Inflammatory skin nodules arise from inflamed blood vessels (vasculitis) or adipose tissue (panniculitis). Either can arise in response to underlying infection or antigen stimulation with influx of inflammatory cells. Vasculitis is categorized by vessel size and circulating immune complexes. Damage to blood vessels results in leakage of red blood cells with the development of purpura (nonblanching red to purple lesions; Chapter 278). Erythema elevatum diutinum is manifested as multiple, infiltrated pink, yellow, red, or violaceous nodules or papules that may be painful or asymptomatic. The lesions can coalesce to form gyrate lesions on the dorsum of the hands or extensor surfaces similar to granuloma annulare. Erythema elevatum diutinum is associated with upper respiratory infections (especially *Streptococcus* species),

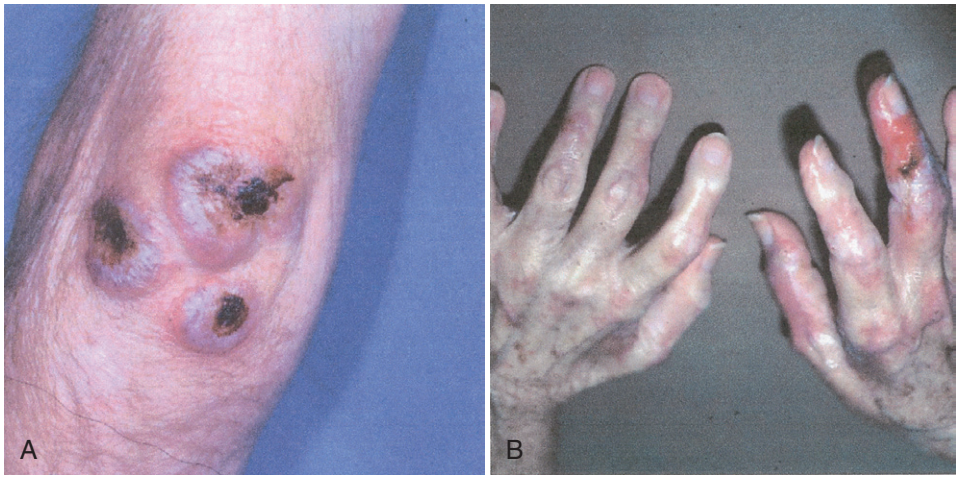

FIGURE 448-22. Sweet's syndrome. A and **B,** Sweet's syndrome in patients with leukemia.

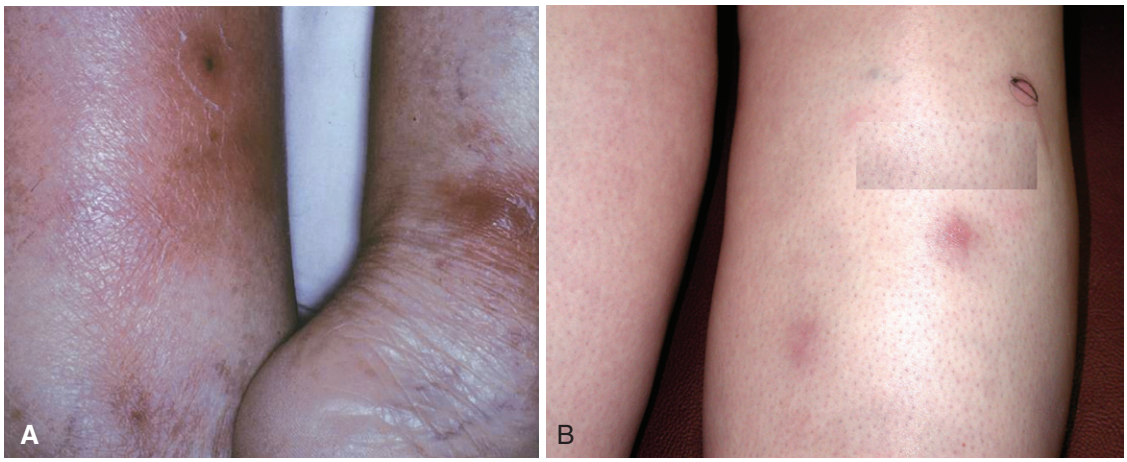

FIGURE 448-23. Erythema nodosum. A and **B,** Erythema nodosum and septal panniculitis of the lower extremities.

HIV infection, and inflammatory bowel disease. The underlying histopathology is a necrotizing vasculitis with neutrophils and hyalinization of the vessels. Erythema elevatum diutinum must be distinguished from Sweet's syndrome, which is characterized by similar lesions clinically (Fig. 448-22). Sweet's syndrome is accompanied by fever, and biopsy specimens show sheets of leukocytes filling the upper dermis in the absence of infection. It occurs in patients with leukemia, inflammatory bowel disease, or rheumatoid arthritis. Sweet's syndrome, but not erythema elevatum diutinum, is highly responsive to corticosteroids, whereas dapsone can improve both conditions.

Polyarteritis Nodosa and Panniculitis

Polyarteritis nodosa (Chapter 278) arises in larger arterioles and may be associated with hepatitis C infection, mesenteric aneurysms, cryoglobulinemia, cutaneous ulceration, and livedo reticularis. Polyarteritis nodosa is distinct from small vessel leukocytoclastic vasculitis, which is characterized by smaller areas (a few millimeters) of purpura.

In the clinical setting, *panniculitis* occurs more frequently than nodular vasculitis. The diagnosis of vasculitis versus septal or lobular panniculitis requires an excisional biopsy, including fat, with appropriate cultures and stains.

Erythema nodosum (Fig. 448-23) is a septal panniculitis characterized by tender nodules that are 1 to 2 cm in diameter with warm, pink, overlying epidermis. They appear in crops on the extremities. A perivascular inflammatory infiltrate is present around small intralobular vessels without vasculitis. Erythema nodosum frequently arises in response to various infections, inflammatory bowel disease, or drug use, but often the underlying cause remains unknown (Table 448-6).

Lobular panniculitis with necrosis and purpura is called nodular vasculitis or erythema induratum. Nodular vasculitis is characterized by painful, chronic recurrent nodules on the shin or thighs that become bluish, ulcerate, and heal with scarring. Erythema induratum (Fig. 448-24) is exacerbated by cold exposure and is sometimes associated with *Mycobacterium tuberculosis* (Chapter 333). True lobular panniculitis, with or without fat necrosis, is more frequent in males with underlying pancreatitis (Chapter 146) and may precede pancreatic cancer (Chapter 200). The lesions have a predilection for the anterior aspect of the shins and may be fluctuant as a result of fat necrosis. *Lupus panniculitis,* or lupus profundus, which involves the fat, is diagnosed by overlying granular immune complex deposition of IgM along the dermal-epidermal junction and must be distinguished from subcutaneous T-cell lymphomas. Lupus panniculitis of the breast, which can be mistaken for adenocarcinoma, is treated with antimalarials or corticosteroids. Lobular panniculitis with calcification of the small arterioles, which occurs in the setting of renal failure with hyperparathyroidism, is called calciphylaxis (Chapter 132).

TABLE 448-6 TRIGGER FACTORS ASSOCIATED WITH ERYTHEMA NODOSUM

Infections
Bacterial: *Streptococcus,* tuberculosis, leprosy, *Mycoplasma, Yersinia, Salmonella,* leptospirosis, tularemia
Fungal: coccidioidomycosis, blastomycosis, histoplasmosis, dermatophytosis
Viruses and *Chlamydia:* paravaccinia, Epstein-Barr virus, lymphogranuloma venereum, cat-scratch disease, psittacosis, hepatitis B
Drugs: sulfonamides, bromides, oral contraceptives
Malignancies: lymphoma, leukemia, carcinoma, after tumor radiation
Inflammatory: ulcerative colitis, Crohn's disease, Whipple's disease, Behçet's syndrome, Sweet's syndrome, collagen vascular diseases
Pregnancy

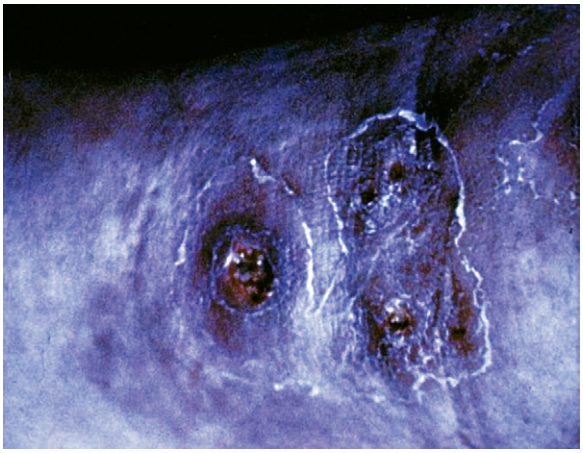

FIGURE 448-24. Erythema induratum.

FIGURE 448-25. Atrophic skin in Ehlers-Danlos syndrome type 2.

Fungal Infections

In immunocompromised patients, necrotic or granulomatous lobular panniculitis can be caused by disseminated fungal infections with *Candida, Sporothrix schenckii, Cryptococcus, Histoplasma, Nocardia, Rhizopus, Aspergillus, Fusarium,* or chromomycosis. Fungal mycelia invade vessel walls, where they produce purpuric and painful lesions that may ulcerate. Osler's nodes, which are tender nodular vasculitic lesions on the extremities, occur in the setting of bacterial endocarditis (Chapter 76). Staphylococcal or streptococcal sepsis may be manifested as pustules, papules, or panniculitic lesions. *Klebsiella* and *Pseudomonas* species are associated with hemorrhagic necrosis of vessels or ecthyma gangrenosa. Granulomatous lobular panniculitis may also arise in the setting of syphilis, atypical mycobacterial infection, tuberculosis, or leprosy.

ATROPHIC AND SCLEROTIC LESIONS

Atrophic Lesions

Atrophic lesions result from thinning or loss of the epidermal and dermal layers (Table 448-7). Examples are photoaging due to loss of epidermal thickness and collagen, discoid lupus, and genetic disorders of collagen production (e.g., Ehlers-Danlos syndrome; Fig. 448-25). Epidermal wrinkling can result in a cigarette paper appearance with prominence of the underlying blood vessels. High-potency topical corticosteroids cause loss of collagen resulting in atrophy. In Cushing's syndrome (Chapter 234), striae appear as red or purple streaks because the underlying dermis can be seen through the epidermis.

Aging skin is most pronounced in sun-exposed areas, but intrinsic aging beginning as early as 30 years of age is characterized by abnormalities in the formation of elastin fibers. Aging of the skin is accompanied by decreased rete ridges and diminished circulation. Sunlight ages the skin by inducing proteolytic enzymes that digest the underlying collagen and elastin (wrinkles). These changes can be partially prevented or restored with the use of topical vitamin A creams on a regular basis and with use of sun protection, including sunscreen. In addition, sun exposure induces pigment incontinence (freckling), increased junctional nevi, and proliferation of benign keratinocyte growths (seborrheic keratoses).

Atrophy can also result from ongoing inflammatory processes that cause scarring, such as collagen vascular disease or mycosis fungoides. The cutaneous and discoid forms of lupus erythematosus (Chapter 274) are manifested as scaly plaques with atrophy or alopecia on sun-exposed areas; the systemic form is characterized by malar rash, urticaria, or vasculitic lesions. Dermatomyositis (Chapter 277) can be associated with collagen vascular disease or malignancy; periorbital suffusion, telangiectasia of the nail beds, and Gottron's papules or scaly lesions over the joints are the skin manifestations. Anetodermas are localized sclerotic lesions (Fig. 448-26) with distinctive clinical features, from underlying inflammation.

Eosinophilic fasciitis is accompanied by nodules or sclerosis of the lower extremities, myopathy, pulmonary disease, and eosinophilia. This syndrome, which follows the ingestion of L-tryptophan or its contaminants, resembles the panniculitis seen in systemic sclerosis, in which fat lobules are replaced by new collagen formation. Eosinophilic cellulitis, or Wells' syndrome, is manifested as nodules, papules, or ulcerative lesions, as well as red plaques where eosinophils infiltrate the area between collagen fibers.

TABLE 448-7 ATROPHIC SKIN CONDITIONS WITH SCARRING, ULCERATIONS, AND/OR TELANGIECTASES

ATROPHY
Epidermal: chronic corticosteroid use, photoaging, mycosis fungoides
Dermal elastin: anetoderma, cutis laxa, intrinsic aging
Dermal collagen: Ehlers-Danlos syndrome, aging
Subcutaneous: granulomatous slack skin (a mycosis fungoides variant)
Lipodystrophy (loss of fat)
SCARRING OR ATROPHY WITH TELANGIECTASIAS
Discoid and subacute cutaneous lupus erythematosus
Dermatomyositis
Keloid formation
Large plaque parapsoriasis (poikiloderma vasculare atrophicans variant of mycosis fungoides)
Photoaging
Necrobiosis lipoidica diabeticorum
Radiation dermatitis
Porphyrias
Thermal burns (erythema ab igne)
SCLEROSIS OR INFILTRATIVE PROCESSES
Amyloidosis
Systemic sclerosis, scleroderma
Localized sclerosis, morphea
Lichen sclerosis et atrophicus
Lichen myxedematosus/papular mucinosis (mucopolysaccharide deposition with paraproteinemia)
Myxedema (mucin deposits with anti–thyroid-stimulating hormone receptor antibodies)
ULCERATIONS
Secondary breakdown of any blister or nodule: infectious, inflammatory, tumor, vasculitis
Decubitus or pressure ulcers
Genital ulcers: syphilis, herpes simplex, chancroid, lymphogranuloma venereum, Behçet's syndrome
Pyoderma gangrenosum, Sweet's syndrome

Sclerotic Lesions

Sclerotic lesions are accompanied by more collagen production, which results in skin with a glossy appearance. Sclerosis may also result from the accumulation of mucopolysaccharides in scleromyxedema (lichen myxedematosus) or from amyloid deposits. An entity associated with renal failure and gadolinium exposure, nephrogenic fibrosing dermopathy (Fig. 448-27) is also characterized by acral fibrosis and deposition of hyaluronate in the skin. In scleroderma (Chapter 275), increased collagen deposition may be associated with Raynaud's syndrome, calcinosis, and telangiectasia. A localized form of scleroderma, termed *morphea,* may occur down the center of the face (coup de

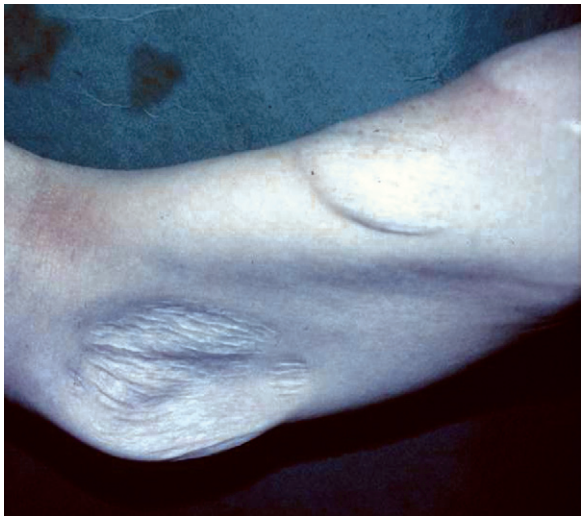

FIGURE 448-26. Anetoderma.

FIGURE 448-27. Nephrogenic fibrosing dermopathy.

sabre), or as plaques on the extremities (Fig. 448-28), after radiation exposure, or with *Borrelia* species infection. Lichen sclerosis et atrophicus is a superficial inflammatory morphea characterized by white atrophic patches, especially in the genital region. Widespread systemic sclerosis may also follow bone marrow transplantation in the setting of chronic graft-versus-host disease.

Telangiectasia

Telangiectasia is prominence of skin blood vessels that frequently accompanies atrophic as well as sclerotic processes and is common in photoaged skin and following radiation therapy. Telangiectasia of the mucous membranes is found in Osler-Weber-Rendu syndrome, and vascular spiders are found both in α_1-antitrypsin deficiency and alcoholic liver disease. The presence of telangiectasia, hyperpigmentation, and hypopigmentation (poikiloderma) in sun-shielded areas of the body should alert the clinician to the diagnosis of early mycosis fungoides.

Ulcers

Ulcers are secondary skin lesions that may arise from trauma, loss of proper blood supply, aging, vasculitis, blister formation, infection, or underlying neoplasia. Ulcers may be shallow erosions (loss of the epidermis) or may be deeper and involve the dermis and underlying subcutaneous structures. Ulcers most commonly appear on the lower extremities, where they result from stasis dermatitis and venous insufficiency, arteriolar insufficiency, diabetic neuropathy, or vasculitis. *Pyoderma gangrenosum* is a trauma-induced ulcer that is part of the spectrum of Sweet's syndrome, accompanies other conditions, and may require immunosuppressive therapy. In contrast, decubitus ulcers require débridement, elimination of local pressure, and attention to nutrition. Diagnosis requires skin biopsy, cultures, and serologic testing for other associated diseases.

FIGURE 448-28. Linear morphea.

After an inflammatory or ulcerated skin wound heals, scarring is common. Epidermal stem cells that reside in the bulge region of the hair follicle are capable of regenerating a normal epidermis. When a wound is deeper than the bulge region, scarring and loss of hair are likely to occur. Scarring alopecia (lichen planopilaris, discoid lupus, scarring folliculitis) results in permanent baldness and must be distinguished from the less severe, nonscarring conditions such as telogen effluvium or alopecia areata. Scarring also accompanies the most severe epidermolysis bullosa disorders caused by sub-basement membrane defects in proteins. Scarring accompanies third-degree burns, deep cryotherapy, or other trauma to the dermis. Scarring may also follow severe inflammation (discoid lupus) or infection (syphilis, leprosy).

Keloids

Some individuals have more pronounced and hypertrophic scar formation known as keloids, with an autosomal dominant inheritance pattern. Keloids are tumor-like in appearance and result from an overproduction of collagen. They are especially common on the anterior of the chest, neck, and earlobes and may require antineoplastic treatment after surgical removal.

449 INFECTIONS, HYPER- AND HYPOPIGMENTATION, REGIONAL DERMATOLOGY, AND DISTINCTIVE LESIONS IN BLACK SKIN

JEAN BOLOGNIA

INFECTIONS, INCLUDING CELLULITIS

Cutaneous infections can be divided into four major categories: bacterial, fungal (Chapter 446), viral, and parasitic (Table 449-1).

Bacterial Infections

Of the bacterial infections, impetigo, folliculitis, furuncles, and cellulitis are most commonly encountered.

IMPETIGO

Impetigo, which is caused by *Staphylococcus aureus* or group A β-hemolytic streptococci, is usually seen as honey-colored crusts (Fig. 449-1); less often, subcorneal (superficial) bullae are present. This infection is most commonly found on the face in children, but it can develop at any site where the cutaneous barrier has been disrupted (e.g., areas of dermatitis, sites of trauma, or arthropod bites). A deeper, but less common, bacterial infection of the skin is *ecthyma*, which is most frequently streptococcal in origin; it is characterized by thick hemorrhagic crusts overlying erosions or ulcerations, usually 0.5 to 1.5 cm in diameter. These lesions favor the extremities, especially in the setting of lymphedema. Ecthyma should not be confused with ecthyma gangrenosum, which represents an embolic phenomenon most often caused by bacteremia with gram-negative bacilli. Although mild cases of impetigo usually respond to topical mupirocin, oral antibiotics that cover *S. aureus* (e.g., dicloxacillin, 250 mg orally four times a day, or cephalexin, 250 mg orally four times a day) are needed to treat more severe impetigo and ecthyma. Compared with furuncles and abscesses, impetigo is less often due to methicillin-resistant *S. aureus*.

TABLE 449-1 SKIN INFECTIONS

BACTERIAL DISEASES
Impetigo
Ecthyma
Folliculitis
Furuncle/carbuncle
Abscess
Erysipelas
Cellulitis
Necrotizing fasciitis
Ecthyma gangrenosum
Other
Gram-negative cocci: meningococcemia, gonococcemia
Gram-positive bacilli: erythrasma, anaerobic cellulitis
Spirochetes: Lyme disease, syphilis, endemic treponematoses
Mycobacteria
VIRAL DISEASES
Herpes simplex virus: oral, genital
Human papillomavirus: common warts, condyloma acuminata
Poxvirus: molluscum contagiosum
Varicella-zoster virus
Viral exanthems (e.g., enteroviruses, rubeola, rubella, parvovirus, Epstein-Barr virus, adenovirus, human immunodeficiency virus)
FUNGAL DISEASES
Candidiasis
Tinea (dermatophytoses): pedis, corporis, cruris, manuum, capitis
Pityriasis (tinea) versicolor
Emboli (e.g., *Aspergillus, Mucor* species)
ECTOPARASITES/PARASITES
Scabies
Lice: scalp, pubic, body
Leishmaniasis
Schistosomiasis, human and animal
Onchocerciasis
Strongyloidiasis
Amebiasis
Trypanosomiasis
Hookworm infections, human and animal
Filariasis
Acanthamoebiasis

FOLLICULITIS

The initial lesions of folliculitis are perifollicular pustules that are often surrounded by a rim of erythema (Chapter 447). *Pseudomonas* folliculitis, which favors the trunk, is usually associated with the use of hot tubs or whirlpools because their higher temperatures (vs. swimming pools) make eradication of *Pseudomonas* more difficult (see Fig. 447-20 in Chapter 447).

FURUNCLES

Furuncles, also called boils, represent *S. aureus* cutaneous infections that are localized primarily within the dermis. In contrast to folliculitis, the lesions are larger and manifest as tender erythematous nodules (Fig. 449-2). A central follicular structure may be noted, as may a central pustule ("pointing"). Because a furuncle is an abscess, the preferred treatment is incision and drainage■ followed by oral antistaphylococcal antibiotics (e.g., dicloxacillin, 250 mg orally four times a day, or cephalexin, 250 mg orally four times a day);

FIGURE 449-1. Impetigo in an infant and marked involvement of the face with honey-colored crusts and superficial erosions. (Courtesy of Yale Dermatology Residents' Slide Collection.)

FIGURE 449-2. Furuncle with surrounding cellulitis. (Courtesy of Yale Dermatology Residents' Slide Collection.)

FIGURE 449-3. Bullous and hemorrhagic cellulitis of the shin. (Courtesy of University of Southern California Dermatology Residents' Slide Collection.)

FIGURE 449-4. Erysipelas of the face with well-demarcated erythematous plaques. (Courtesy of Yale Dermatology Residents' Slide Collection.)

if methicillin-resistant *S. aureus* is likely (e.g., use of health care facilities such as dialysis units, participation in skin-to-skin contact sports, an elevated prevalence of methicillin-resistant isolates in the local community), the antibiotic should be changed to clindamycin (300 to 450 mg orally four times daily), doxycycline (100 mg orally twice daily), minocycline (100 mg orally twice daily), trimethoprim-sulfamethoxazole (160 mg/800 mg orally twice daily), or linezolid (600 mg orally every 12 hours). The duration of therapy is usually 10 to 14 days. *Carbuncles* are larger, more complex, and more extensive versions of furuncles; they may be accompanied by systemic symptoms such as fever and may require a more prolonged course of therapy.

CELLULITIS

Cellulitis is a fairly common cutaneous infection that occurs most often on the lower extremities. Locally, it manifests as erythema, edema, warmth, and tenderness; systemic findings can include fever, malaise, and leukocytosis. Most cases are bacterial in origin, but some are caused by fungal infections (e.g., *Cryptococcus* species) or chemical reactions (e.g., extravasated oxacillin or calcium salts). Bacterial cellulitis is most commonly caused by group A β-hemolytic streptococci and *S. aureus*, with the former being associated with the more severe, necrotizing variant. In patients who have diabetes or who are immunocompromised, cellulitis can be caused by gram-negative bacilli or atypical mycobacteria. Risk factors include a preceding break in the skin barrier, edema secondary to venous hypertension, lymphedema, and previous bouts of cellulitis.

Although the diagnosis of cellulitis is usually fairly straightforward (Fig. 449-3), it can sometimes be difficult in patients with chronic lower extremity edema, especially those who are afebrile. One complication of chronic lower extremity edema is lipodermatosclerosis (i.e., inflammation followed by fibrosis of subcutaneous fat), which is seen acutely as erythema, warmth, and tenderness and is easily confused with cellulitis. The skin above the medial malleolus is often the initial site of involvement with lipodermatosclerosis, but the inflammation can extend onto the shin and calf. The chronic phase of lipodermatosclerosis is characterized by induration, a permanent brown-red to violet discoloration of the skin, and an "inverted wine bottle" appearance of the distal end of the lower extremity. It is important for the clinician to realize that in patients with chronic lipodermatosclerosis and superimposed cellulitis, the skin will never return to its normal color, even after adequate antibiotic therapy.

Unless there is an associated bacteremia, the diagnosis of cellulitis is primarily clinical. In immunocompromised hosts, a saline injection followed by aspiration and culture can be helpful. Histologically, cellulitis is characterized by an infiltrate of neutrophils within the dermis. Skin biopsy can exclude disorders that may be confused with cellulitis, such as contact dermatitis, erythema migrans, inflammatory carcinoma, toxic erythema of chemotherapy, and Wells' syndrome (an idiopathic disorder in which eosinophils infiltrate the dermis). Treatment of cellulitis varies from oral cephalexin to intravenous vancomycin plus intravenous ceftazidime, depending on the suspected pathogens, the host, and the severity of systemic toxicity.

Cellulitis resides in the middle of a spectrum of soft tissue infections that includes *erysipelas* (more superficial and more sharply demarcated; Fig. 449-4) at one end and *necrotizing fasciitis* (deeper, more necrotic, and undermining) at the other. In healthy adults, erysipelas can be treated with oral penicillin (200,000 units four times daily) or, if methicillin-sensitive *S. aureus* is of concern, oral dicloxacillin (500 mg four times daily) for a 10-day course. Necrotizing fasciitis is usually caused by multiple organisms, including anaerobic streptococci; its diagnosis requires a high index of suspicion, and it must be considered when there are areas of violaceous induration or a foul-smelling discharge. Prompt surgical débridement and broad-spectrum systemic antibiotics (e.g., a β-lactam/β-lactamase inhibitor such as intravenous piperacillin-tazobactam, 4.5 g every 6 hours for a total of 18 g/day [16 g piperacillin/2 g tazobactam]), with or without ciprofloxacin (500 mg orally or 400 mg intravenously every 12 hours), for at least 2 weeks are mandatory. Unless only a single organism is seen on Gram stain and isolated on culture, broad-spectrum antibiotic coverage should be continued because of the polymicrobial nature of necrotizing fasciitis and the difficulty of culturing anaerobes.

Although *Clostridium perfringens* can cause anaerobic cellulitis and gas gangrene, the most common cutaneous infection by gram-positive bacilli is *erythrasma*, which is manifested as interdigital toe web maceration with fissures, as well as shiny or scaly brown-red patches in the axillae and groin. The latter is often confused with tinea cruris (Chapter 446). A diagnostic finding is the presence of coral (orange-pink) fluorescence on Wood's lamp illumination (ultraviolet A). The responsible organism is *Corynebacterium minutissimum*. Treatment options include topical and oral erythromycin (e.g., 333 mg three times a day for 7 to 14 days).

TOXIC ERYTHEMAS

Eruptions caused by the release of toxins (e.g., exfoliative toxins ET-A and ET-B) produced by *S. aureus* and streptococci include *staphylococcal scalded skin syndrome* (Chapters 296 and 447), *scarlet fever* (Chapter 298), and *toxic shock syndrome* (Chapter 447). Staphylococcal scalded skin syndrome (see Fig. 447-14 in Chapter 447) is characterized by large areas of tender erythema in which superficial desquamation (peeling) develops, often with scaling and crusting in a radial array around the mouth. The areas of erythema are sterile; the conjunctivae, nasopharynx, or a distant site on the skin is the usual site of the primary staphylococcal infection. A clue to the diagnosis of scarlet fever is the presence of a strawberry tongue with prominent red papillae. Management involves treatment of the systemic infection (Chapters 296 and 447).

NEISSERIA INFECTIONS

Both *gonococcemia* (Chapter 307) and *meningococcemia* (Chapter 306) can present with cutaneous lesions. The former gives rise to a small number of vesicopustules on an erythematous base, generally acral in location (Fig. 449-5); these lesions represent septic emboli and are accompanied by fever, arthritis, and tendinitis. The earliest lesions of *acute meningococcemia* may be subtle (macular areas of erythema), but central hemorrhage (petechiae and purpura) and necrosis (gun-metal gray color) soon follow (Fig. 449-6). The lesions may become quite extensive; when accompanied by disseminated intravascular coagulation, severe peripheral ischemia may result. Cutaneous involvement in *chronic meningococcemia* is a reflection of lymphocytic or leukocytoclastic vasculitis rather than septic emboli. Management is systemic treatment (Chapters 306 and 307).

PSEUDOMONAS INFECTIONS

Pseudomonas infections of the skin vary from "hot tub" folliculitis (Chapter 447) to soft tissue infections of the external ear. Interdigital toe web infections that begin as simple tinea pedis can be complicated by superimposed

FIGURE 449-5. Disseminated gonococcal infection with an acral pustule on a red-violet base. (Courtesy of Yale Dermatology Residents' Slide Collection.)

FIGURE 449-6. Purpuric and necrotic embolic lesions of meningococcemia. (Courtesy of Yale Dermatology Residents' Slide Collection.)

Pseudomonas infection and result in erythema, swelling, tenderness, and drainage. Depending on its severity, treatment varies from topical antiseptics to oral or intravenous fluoroquinolones (e.g., ciprofloxacin, 500 mg orally every 12 hours for 7 to 14 days). In immunocompromised hosts, *Pseudomonas* and other gram-negative bacilli can produce cellulitis as well as secondary septic emboli in the skin. The latter begin as purpura or purpuric bullae in which central necrosis then develops. These lesions, which arise as a result of ischemic infarction of the skin, are termed *ecthyma gangrenosum*. Management is treatment of the systemic pseudomonal disease (Chapter 314).

SPIROCHETES

Spirochetal infections have a wide range of skin findings, from erythema migrans secondary to *Borrelia burgdorferi* (Chapter 329), to endemic treponematoses such as *yaws* and *pinta* (Chapter 328), to the cutaneous manifestations of the three stages of *syphilis* (Chapter 327). Syphilitic lesions include a firm, generally nontender ulceration (chancre) in primary syphilis; a generalized papulosquamous eruption (Chapter 446) plus alopecia, oral ulcers, and condylomata lata in secondary syphilis; and thick plaques and ulcers in tertiary disease. Management involves treatment of the systemic disease.

MYCOBACTERIA INFECTIONS

Infections with *Mycobacterium tuberculosis* and mycobacteria other than *M. tuberculosis* (atypical mycobacteria) are associated with skin lesions, including verrucous or crusted papules, scarring granulomatous plaques, and draining ulcers. In immunocompetent hosts in developed countries, *Mycobacterium marinum* (Chapter 333) is most commonly associated with skin disease, which is usually manifested in a lymphocutaneous (i.e., sporotrichoid) pattern. Treatment of cutaneous mycobacterial disease (Chapters 332 and 333), including leprosy (Chapter 334), is the same as for systemic disease.

FIGURE 449-7. Scabies with involvement of the penis. (From Bolognia J, Jurizzo J, Rapini R, et al. *Dermatology,* 2nd ed. Edinburgh: Mosby; 2007.)

Viral Infections

The most common viral infections of the skin are verrucae (warts; see Fig. 447-2 in Chapter 447), recurrent oral and genital herpes simplex (Chapters 382 and 447), molluscum contagiosum (see Fig. 448-9 in Chapter 448), and exanthems (Chapter 447). Varicella and herpes zoster are seen less frequently (Chapter 383).

Fungal Infections

A variety of fungal infections involve the skin and nails and are most commonly due to dermatophytes (tinea), *Candida* species, and *Malassezia* species (pityriasis versicolor) (Chapter 446; also see Table 449-1). Although both dermatophyte infections and pityriasis versicolor are associated with scaling, cutaneous candidiasis is characterized by erythema, a more erosive quality, and satellite pustules. Treatment is described in Chapter 446.

Septic emboli caused by *Candida* or other opportunistic fungi such as *Aspergillus* (Chapter 347) or *Fusarium* often have a clinical appearance similar to that of ecthyma gangrenosum secondary to gram-negative rods such as *Pseudomonas*. The responsible organisms can be detected histologically in biopsy specimens or by bedside examination of dermal scrapings; culture confirms the specific organism. Cutaneous plaques secondary to *Pneumocystis jirovecii* favor the internal ear. Treatment is for the underlying fungal infection.

Ectoparasites and Parasites

ECTOPARASITES: SCABIES AND LICE

The most common ectoparasitic cutaneous infestations are (1) scabies from the human variant of the *Sarcoptes* mite and (2) lice, of which there are three subtypes: head, body, and pubic. *Scabies* is characterized by pruritus in association with papules, papulovesicles, and linear burrows, as well as signs of scratching, such as excoriations and areas of dermatitis. Sites of predilection include the wrists, ankles, fingers, toes (including the web spaces), areolae, and genitalia (especially the penis) (Fig. 449-7). The number of mites living within the stratum corneum is limited in immunocompetent hosts; when scraped and examined microscopically, linear burrows provide the highest yield of mites and eggs. In elderly and immunosuppressed patients, a form of scabies known as crusted or Norwegian scabies presents as multiple areas of scaling and crusting that are teeming with mites.

Infestations with scalp *lice* are seen most commonly in children, who may be asymptomatic or have marked pruritus. In addition to the lice, multiple egg casings ("nits") are attached to the proximal portions of scalp hairs. In developed countries, body lice are seen primarily in homeless individuals; patients typically have multiple erythematous papules at the sites of "bites," as well as signs of scratching. The lice and their eggs are found in the patient's

clothing. Pubic lice are sometimes called "crabs" because their bodies are shorter and broader than those of scalp or body lice and thus resemble the shape of a crab. As a result of their leg span, these lice reside primarily on pubic hairs and less often on axillary hairs or eyelashes.

The most effective U.S. Food and Drug Administration–approved treatments of head lice, pubic lice, and routine scabies are topical 0.5% malathion, 5% permethrin cream,[2] and 5% permethrin cream, respectively; each of these topical medications is applied for 8 to 12 hours on days 1 and 8. For crusted scabies, oral ivermectin (250 to 400 µg/kg; off-label use) is often required to eradicate the infestation.[■] Treatment of body lice involves discarding egg- and lice-infested clothing; for head lice, potential sources of reinfection, such as hairbrushes, should be discarded. Sexual and household contacts of patients with pubic lice and scabies, respectively, must be treated similarly to the symptomatic patient.

OTHER PARASITES

Cutaneous lesions are seen in leishmaniasis (Chapter 356), amebiasis (Chapter 360), schistosomiasis (Chapter 363), onchocerciasis (Chapter 366), strongyloidiasis (Chapter 365), and hookworm infections (Chapter 365). Exposure to water infested with the cercariae of animal schistosomes results in multiple erythematous papules, which occur most commonly on the feet and are termed *swimmer's itch*. Dog and cat hookworm infections lead to *cutaneous larva migrans*, with serpiginous erythematous tracks that correspond to the path of migration of the hookworm larvae. Both these infections are self-limited because the parasite's life cycle cannot be completed in humans. In immunocompromised hosts, cutaneous plaques can occasionally develop from free-living amebae such as *Acanthamoeba*.

DISORDERS OF HYPOPIGMENTATION AND HYPERPIGMENTATION

Disorders of pigmentation can be divided into four major categories: diffuse, linear, circumscribed, and either reticulated (in the case of hyperpigmentation) or guttate (in the case of hypopigmentation) (Table 449-2).

TABLE 449-2 DISORDERS OF PIGMENTATION

HYPOPIGMENTATION
Diffuse (Pigmentary Dilution)
Oculocutaneous albinism Hermansky-Pudlak syndrome Chédiak-Higashi syndrome Generalized (total) vitiligo Inborn errors of metabolism (e.g., phenylketonuria)
Circumscribed
Decrease in pigment Acquired: postinflammatory hypopigmentation (e.g., atopic dermatitis, sarcoidosis, systemic lupus erythematosus, mycosis fungoides), pityriasis (tinea) versicolor secondary to *Malassezia* spp infection Congenital: nevus depigmentosus, ash-leaf spots of tuberous sclerosis Absence of pigment Acquired: vitiligo, chemical leukoderma, leukoderma of scleroderma, leukoderma of melanoma Congenital: piebaldism
Linear
Nevoid linear hypopigmentation (previously referred to as hypomelanosis of Ito)
Guttate
Idiopathic guttate hypomelanosis Confetti macules of tuberous sclerosis
HYPERPIGMENTATION
Diffuse
Drug reactions (e.g., cyclophosphamide, busulfan) Addison's disease Ectopic adrenocorticotropic hormone production (e.g., small cell lung cancer) Hemochromatosis Scleroderma Primary biliary cirrhosis Hyperthyroidism Vitamin B_{12} or folate deficiency Porphyria cutanea tarda Melanosis secondary to metastatic melanoma Argyria (gray hue)
Circumscribed
Postinflammatory hyperpigmentation (e.g., acne vulgaris, arthropod bites, dermatitis, lichen planus) Melasma Pityriasis (tinea) versicolor Mastocytosis Fixed drug reactions Deposits of drugs and their metabolites
Linear
Exposure to psoralen-containing plants (e.g., limes) plus ultraviolet A light Drug reactions (e.g., bleomycin) Nevoid linear hyperpigmentation Genodermatoses (e.g., incontinentia pigmenti)
Reticulated
Erythema ab igne Genodermatoses

Hypopigmentation

ALBINISM

The primary disorder of diffuse hypopigmentation is *oculocutaneous albinism*, an autosomal recessive disorder in which there is a pigmentary dilution of melanin-containing structures (i.e., the eyes, hair, and skin). The phenotype varies from total absence of melanin pigment to a subtle decrease whose recognition requires comparison with first-degree relatives; the density of melanocytes in skin is normal, but their ability to produce pigment is absent or decreased. Ninety percent of patients with oculocutaneous albinism have mutations in the genes that encode either tyrosinase (type I) or P protein (type II). Complications of oculocutaneous albinism include decreased visual acuity, nystagmus, photophobia, and an increase in cutaneous carcinomas, especially squamous cell carcinoma. These signs and symptoms are most severe in those who produce the least pigment. The differential diagnosis includes total vitiligo (absence of melanocytes histologically) and a few inborn errors of metabolism (e.g., phenylketonuria). Treatment consists of longitudinal ophthalmologic care and minimizing sun exposure.

LINEAR HYPOPIGMENTATION

Disorders of *linear hypopigmentation* consist primarily of nevoid conditions (e.g., nevoid linear hypopigmentation, hypomelanosis of Ito, segmental or systematized nevus depigmentosus) in which streaks of hypomelanosis follow Blaschko's lines (an embryonic development pattern that involves all layers of the skin and becomes clinically apparent in the setting of mosaicism). A minority of patients have associated central nervous system and musculoskeletal abnormalities.

CIRCUMSCRIBED (PATCHY) HYPOPIGMENTATION

Vitiligo

Vitiligo (Fig. 449-8) is usually slowly progressive and occurs principally in periorificial areas (around the eyes, nose, lips, genitalia) and the hands, feet, flexor surface of the wrists, ankles, elbows, knees, and major body folds. Vitiligo, which is caused by a loss of melanocytes within the skin, is also associated with autoimmune endocrinopathies (Chapter 239) and alopecia areata (see later). T cells that recognize antigens on the surface of melanocytes (and melanoma cells) are found within the skin and in peripheral blood. Treatment includes topical corticosteroids, topical immunomodulators (e.g., tacrolimus), and phototherapy.[■] The differential diagnosis is primarily chemical leukoderma secondary to compounds that are cytotoxic to melanocytes (e.g., catechols, phenols), the leukoderma of melanoma (a good prognostic sign if seen in association with immunotherapy but an indication to exclude metastases if occurs spontaneously), and the leukoderma of scleroderma with retention of perifollicular pigmentation.

Guttate Hypopigmentation

Idiopathic guttate hypomelanosis, in which well-demarcated hypopigmented macules measure only 2 to 4 mm in diameter, is the most common cause of guttate ("raindrop") leukoderma (Fig. 449-9). The favored sites for this common age-related disorder, which may be related to chronic sun exposure, are the shins and the extensor surface of the forearms.

Other Acquired Causes

Circumscribed hypomelanosis is seen in patients with pityriasis (tinea) versicolor (see Fig. 446-16) and *postinflammatory hypopigmentation*. Although

FIGURE 449-8. Striking leukoderma of the hand in a patient with vitiligo.

FIGURE 449-9. Idiopathic guttate hypomelanosis with small, well-demarcated hypopigmented macules on the shin.

postinflammatory hypopigmentation is most often associated with atopic dermatitis, it can also occur with sarcoidosis (Chapter 95), lupus erythematosus (Chapter 274), and mycosis fungoides (Chapter 191).

Congenital Causes

Congenital circumscribed areas of hypomelanosis include *nevus depigmentosus*, a common tan "birthmark" seen in 1 in 50 infants in which there is a partial decrease in pigment; *piebaldism*, an unusual autosomal dominant disorder with areas of complete absence of pigment caused by mutations in the *KIT* gene; *nevus anemicus*, a localized area of vasoconstriction; and the *ash-leaf spots* of tuberous sclerosis (Chapter 426), with a partial decrease in pigment.

Hyperpigmentation

DIFFUSE HYPERPIGMENTATION

Diffuse hyperpigmentation is most commonly due to drugs (e.g., cyclophosphamide, zidovudine) and endocrinopathies associated with increased circulating levels of adrenocorticotropic hormone (ACTH) (e.g., Addison's disease [Chapter 234], ectopic ACTH production by tumors such as small cell lung carcinoma [Chapter 197]). ACTH, as well as melanocyte-stimulating hormone, can bind and activate the melanocortin-1 receptors on melanocytes, thereby leading to increased melanin production. Additional causes include hemochromatosis (Chapter 219), scleroderma (Chapter 275), primary biliary cirrhosis (Chapter 158), and hyperthyroidism (Chapter 233). Systemic exposure to silver (argyria; Chapter 21) can lead to a slate-gray color.

FIGURE 449-10. Postinflammatory hyperpigmentation secondary to arthropod bites. (Courtesy of Yale Dermatology Residents' Slide Collection.)

FIGURE 449-11. Hyperpigmented patches on the cheek in a patient with melasma.

LINEAR AND RETICULATED HYPERPIGMENTATION

Linear streaks of hyperpigmentation can be due to nevoid (i.e., hamartomatous) conditions that reflect cutaneous mosaicism, as in linear hypopigmentation (see earlier) and genodermatoses (inherited disorders with cutaneous manifestations, e.g., incontinentia pigmenti secondary to mutations in the gene *NEMO*), as well as due to exposure to either plant-derived psoralens (e.g., from limes) plus ultraviolet A irradiation or systemic bleomycin (flagellate pigmentation). Reticulated hypermelanosis is also seen in several genodermatoses (e.g., dyskeratosis congenita) and after chronic exposure to heat (erythema ab igne). The latter corresponds to the cutaneous venous plexus and is seen most commonly in the lumbosacral region where heating pads have been applied or on the anterior thighs from laptop computers.

CIRCUMSCRIBED (PATCHY) HYPERPIGMENTATION

The most common causes of circumscribed hypermelanosis are tinea versicolor (which can present as both hypopigmentation and hyperpigmentation, hence its name), postinflammatory hyperpigmentation, and melasma. *Postinflammatory hyperpigmentation* (Fig. 449-10) is observed more frequently in

darkly pigmented individuals and often follows acne vulgaris, arthropod bites, chronic dermatitis, and lichen planus. Additional causes of circumscribed darkening of the skin are cutaneous mastocytosis (urticaria pigmentosa; Chapter 263), deposits of drugs such as antimalarials and minocycline (blue-gray discoloration), and medications that produce fixed drug reactions, most frequently trimethoprim-sulfamethoxazole and nonsteroidal anti-inflammatory drugs. In *melasma* (Fig. 449-11), symmetrical hyperpigmented patches are seen on the lateral aspect of the forehead, upper part of the cheek, and mandibular area. At least 90% of patients with melasma are women. The lesions are exacerbated by ultraviolet light and estrogen (oral contraceptives, pregnancy). Melasma is treated with daily broad-spectrum sunscreens and lightening agents such as hydroquinone (4% cream) and retinoic acid (0.025 to 0.10% cream) for 3 to 4 months; the creams are applied daily, but should be reduced to alternate days if irritation develops.

DISTINCTIVE LESIONS IN BLACK SKIN

Although some diseases are more common in patients of African ancestry (e.g., tinea capitis, pseudofolliculitis barbae, dissecting cellulitis), others are simply more noticeable (e.g., vitiligo and postinflammatory hypopigmentation) (Table 449-3). The explanation for the increased incidence is speculative in most instances, with the exception of curled hairs leading to pseudofolliculitis barbae. Tightly curled hairs, when shaved, are usually cut at an oblique angle, which results in a sharp tip at the distal end of the hair shaft that allows penetration of the skin adjacent to the hair follicle and subsequent inflammation. Some cutaneous disorders are seen less commonly in black skin (e.g., acne rosacea and scabies).

Another entity seen more commonly in individuals of African descent is keloids (Fig. 449-12). Keloids generally appear at sites of trauma (e.g., ear piercing) but can occasionally develop spontaneously, especially on the trunk. In the former situation, they are thought to represent an exaggerated response to wound healing, with increased formation of collagen not only at the site of the trauma (as in hypertrophic scars) but also in adjacent, previously uninvolved skin. Treatment options include intralesional corticosteroids, intralesional interferon, pulsed dye laser, or excision followed by radiation therapy.

Papular eczema and follicular-based inflammation

*Also termed *follicular degeneration syndrome* or *hot comb alopecia*.

REGIONAL DERMATOSES

Some common dermatoses have a predilection for particular anatomic sites (Fig. 449-13 and Table 449-4). These locations can help narrow the differential and guide further diagnostic testing and therapy in many patients.

FIGURE 449-12. Acne keloidalis in an African American man. (Courtesy of Kalman Watsky, MD.)

TABLE 449-4 REGIONAL DERMATOLOGY

REGION OF SKIN	TYPE OF SKIN LESION	DISEASE PROCESS
Scalp	Papulosquamous and eczematous	Seborrheic dermatitis, psoriasis, tinea capitis, eczema (atopic, contact)
	Pustular	Folliculitis, kerion
	Papulonodular	Melanocytic nevi, seborrheic keratoses, pilar cysts, verrucae
Face	Pustular	Acne, rosacea, folliculitis (beard), tinea
	Papulosquamous and eczematous	Seborrheic dermatitis, psoriasis (hairline), contact dermatitis (e.g., cosmetics), atopic dermatitis, impetigo, systemic lupus erythematosus, photodermatitis
	Vesicular	Herpes simplex, herpes zoster, bullous impetigo
	Papulonodular	Melanocytic nevi, actinic keratoses, seborrheic keratoses, basal cell carcinomas, squamous cell carcinomas, melanomas
	Atrophic and telangiectatic	Discoid lupus erythematosus
Trunk	Papulosquamous and eczematous	Psoriasis, atopic dermatitis, contact dermatitis, tinea versicolor, pityriasis rosea, scabies, secondary syphilis, subacute cutaneous lupus (upper trunk)
	Vesiculobullous	Bullous pemphigoid, pemphigus, erythema multiforme/Stevens-Johnson syndrome, herpes zoster
	Maculopapular	Morbilliform drug reactions, viral exanthems
	Papulonodular	Melanocytic nevi, seborrheic keratoses, angiomas, lipomas, epidermoid inclusion cysts, basal and squamous cell carcinomas, keloids, neurofibromas, melanoma
	Pustular	Acne, folliculitis
	Urticarial	Hives, drug reactions, early herpes zoster
Arms and forearms	Eczematous and papulosquamous	Contact dermatitis (e.g., plants), atopic dermatitis, psoriasis, lichen planus, photodermatitis (drugs, contactants, dermatomyositis, subacute cutaneous lupus)
	Papulonodular	Melanocytic nevi, verrucae, seborrheic keratoses, actinic keratoses, squamous cell carcinomas, polymorphic light eruption
	Purpuric	Actinic (solar) purpura
	Annular	Granuloma annulare, subacute cutaneous lupus

TABLE 449-4 REGIONAL DERMATOLOGY—cont'd

REGION OF SKIN	TYPE OF SKIN LESION	DISEASE PROCESS
Legs	Eczematous and papulosquamous	Stasis dermatitis, eczema craquelé (xerotic eczema), contact dermatitis, atopic dermatitis, psoriasis, lichen planus
	Papulonodular	Melanocytic nevi, dermatofibromas, erythema nodosum, melanoma, Kaposi's sarcoma
	Purpuric	Schamberg's disease (capillaritis), vasculitis
	Ulcerative	Stasis ulcers, arterial insufficiency, pyoderma gangrenosum, trauma, spider bite, livedoid vasculopathy, squamous cell carcinoma, diffuse dermal angiomatosis
Genitalia and groin	Eczematous and papulosquamous	Seborrheic dermatitis, tinea, psoriasis, contact dermatitis, scabies, reactive arthritis (Reiter's syndrome), erythrasma, candidiasis, lichen planus, lichen simplex chronicus
	Vesiculobullous	Herpes simplex, Stevens-Johnson syndrome
	Ulcerative	Herpes simplex, syphilis, chancroid, Behçet's disease, squamous cell carcinoma, trauma
	Papulonodular	Condyloma acuminata, molluscum contagiosum, epidermoid inclusion cyst, hidradenitis suppurativa, squamous cell carcinoma
	Pustular	Folliculitis, candidiasis, hidradenitis suppurativa
Hands	Eczematous and papulosquamous	Irritant and allergic contact dermatitis, atopic dermatitis, tinea, scabies, secondary syphilis
	Vesiculobullous, pustular	Erythema multiforme, hand-foot-and-mouth disease (palmar), porphyria cutanea tarda (dorsal), epidermolysis bullosa acquisita, herpetic whitlow, blistering dactylitis, psoriasis
	Papulonodular	Warts, actinic keratoses (dorsal), squamous cell carcinomas (dorsal), pyogenic granuloma, granuloma annulare, digital mucous cysts (dorsal)
	Depigmentation	Vitiligo, chemical leukoderma
	Periungual telangiectases	Scleroderma, dermatomyositis, systemic lupus erythematosus, Osler-Weber-Rendu disease
Feet	Eczematous and papulosquamous	Tinea, psoriasis, contact dermatitis, atopic dermatitis, syphilis
	Vesiculobullous	Tinea, arthropod bites, epidermolysis bullosa (inherited and acquired), erythema multiforme, hand-foot-and mouth disease, epidermolysis bullosa acquisita
	Papules	Verrucae, corns
	Ulcerative	Neuropathic ulcers (plantar)

450 DISEASES OF HAIR AND NAILS

ANTONELLA TOSTI

HAIR DISORDERS

Normal Hair

The hair shaft is a fully keratinized structure that is produced by the hair follicle. The entire skin, with the exception of the palms and the soles, contains hair follicles. Hair follicles are of two types: terminal follicles and vellus follicles. Terminal follicles, which reach the hypodermis, produce terminal hairs, which are long, thick (60 to 80 μm), and pigmented. Terminal hairs are present since birth on the scalp, eyebrows, and eyelashes and later develop after puberty on the axillae, pubis, and beard region in males. Vellus follicles are small and localized to the superficial and mid-dermis, where they produce vellus hairs, which are thin (<30 μm), short (<2 cm), and not pigmented and cover all the glabrous skin.

The hair follicle is formed by an upper permanent portion and by a lower dynamic transient portion that migrates during the hair cycle. The transient portion includes the hair bulb, which is surrounded by the dermal papilla and contains the hair matrix that produces the hair shaft and its sheaths. The anatomic division between the permanent and the transient portion is just below the bulge region, which corresponds to the insertion of the erector pili muscle. The bulge region contains the epithelial stem cells that regenerate the follicle in each hair growth cycle; its damage results in stem cell destruction and cicatricial alopecia.

Hair Cycle

Hair follicles have a cyclic activity, characterized by alternating periods of hair shaft production and periods of resting (anagen, catagen, telogen). During the anagen phase, the follicles produce the hair shaft. Duration of anagen, which in the scalp ranges from 2 to 7 years, determines hair shaft length. Maximal length and growth rate of terminal hair varies in the different body regions. Scalp hair grows about 0.4 mm/day and may reach a length of more than 1 meter. Maximal hair length decreases with age. Catagen is a transitional phase, which lasts for 2 to 3 weeks and precedes the resting telogen phase. During telogen, hair production is absent, even if the shaft remains within the follicle to be shed only when, after 3 months, the follicle reenters the anagen phase.

The hair cycle of adjacent scalp follicles is not synchronized. In normal conditions, about 85 to 90% of follicles are in anagen and 10 to 15% in telogen.

Hair Loss and Alopecias

Hair loss distresses most patients, independently from its severity and pattern. In some cases, the decrement in quality of life attributable to hair loss is comparable with that caused by major chronic diseases.

The first diagnostic step is to assess family history, drug intake, systemic illness, and severity and duration of hair loss (Table 450-1). The second step is to establish whether the hair density is normal or decreased. The severity of hair shedding should be evaluated, and if possible, the shed hairs should be examined.

Acute and severe hair loss is typical of diseases that acutely interrupt mitotic activity of anagen follicles (drugs, alopecia areata). A normal hair density suggests a diagnosis of telogen effluvium, which may be acute or chronic. A reduced hair density may involve the whole scalp (diffuse alopecia), may be limited to specific scalp regions (patterned alopecia), or may present with bald patches (patchy alopecia). In patchy alopecias, the scalp may show patches of alopecia that are completely devoid of hairs (alopecia areata, cicatricial alopecia) or have short broken hairs (trichotillomania, hair shaft disorders).

TELOGEN EFFLUVIUM

Acute Telogen Effluvium

Acute telogen effluvium results from noxious events that precipitate the entry of a large number of follicles into their resting phase (telogen). Possible causes include systemic diseases, drugs (Table 450-2), fever, stress, weight loss, delivery, iron deficiency, and inflammatory scalp disorders. For drugs, the severity of hair loss depends on the drug, its dosage, and the patient's susceptibility.

Hair loss starts approximately 3 months after the causative event, a time frame that corresponds with the duration of the telogen phase. Telogen hairs are retained within the follicle during telogen, to be shed when the follicle produces a new anagen hair. Hair loss is severe when shedding is 100 to 200 hairs. The patient usually remembers quite precisely when the increased hair shedding started. Acute telogen effluvium does not usually produce visible alopecia because about 50% of hairs need to be lost before reduction of hair density is evident.

TREATMENT AND PROGNOSIS Rx

Acute telogen effluvium subsides spontaneously in a few months after removal of the cause. It may, however, increase the likelihood or severity of subsequent androgenetic alopecia.

Chronic Telogen Effluvium

Chronic telogen effluvium, which is characterized by increased hair shedding lasting for more than 6 months, mostly affects middle-aged women and frequently remains unexplained. The daily shedding is mild (usually less than 100 hairs daily), but patients can be distressed and complain of progressive temporal thinning and decreased hair mass. Scalp pain (trichodynia) is frequently reported. Patients who have a high hair density may even bring in envelopes of shed hairs to prove the amount of hair loss. There is no effective treatment. Chronic telogen effluvium has a chronic course with periodic exacerbations.

DIFFUSE ALOPECIA

Anagen Effluvium

Acute hair shedding leading to diffuse alopecia is a typical side effect of cancer chemotherapy and scalp radiation. Hair shedding is caused by acute damage to the growing hair; the result is hair breaking. Hair loss is acute and severe and may produce loss of most of the scalp hair, eyebrows, and eyelashes;

TABLE 450-2 DRUGS REPORTED TO INDUCE HAIR LOSS

ACE inhibitors (captopril, enalapril, moexipril, ramipril)
Allopurinol
Amiodarone
Amphetamines*†
Analgesics, anti-inflammatories (ibuprofen, indomethacin, naproxen)
Androgens*¶
Anticoagulants (coumarin, dextran, heparin/heparinoids)*†
Antiepileptics (carbamazepine, hydantoins, lamotrigine, troxidone, valproic acid, vigabatrin)*†
Antipsychotics (flupenthixol decanoate, fluphenazine decanoate)
Antithyroid drugs (carbimazole, iodine, thiouracil)*
Appetite suppressants
Aromatase inhibitors (fadrozole, 4-OHA, vorozole)*¶
Benzimidazoles (albendazole, mebendazole)
β-Blockers (levobunolol, metoprolol, nadolol, propranolol, timolol)*
Bromocriptine
Buspirone
Butyrophenones
Cantharidin
Cholestyramine
Chloramphenicol
Cidofovir
Cimetidine
Clonazepam
Clotrimazole
Colchicine
Contraceptives (oral)‖
Danazol
Diclofenac
Dixyrazine
Diazoxide
Ethambutol
Ethionamide
Fibrates (clofibrate, fenofibrate)
Gentamicin
Gefitinib†
Glatiramer acetate
Glibenclamide
Gold salts
G-CSF (granulocyte-colony stimulating factor)
Haloperidol
Immunoglobulins
Indanediones
Indinavir*
Interferons*†
Isonicotinic acid hydrazide§
Leflunomide*
Levodopa

Minoxidil‖
Nicotinic acid
Nitrofurantoin
Octreotide
Olanzapine
Pentosan polysulfate
Phenindione
Piroxicam
Potassium thiocyanate
Pyridostigmine
Radiation (<700 Gy)*§
Retinol (vitamin A)*
Retinoids (acitretin, etretinate, isotretinoin)*†
Risperidone
Salicylates
Serotonin reuptake inhibitors (fluoxetine, fluvoxamine, paroxetine, sertraline)*
Sorafenib
Strontium ranelate*†
Sulfasalazine
Tamoxifen
Terbinafine
Terfenadine
Thiamphenicol
Thyroxine
Tocopherol (vitamin E)
Trazodone
Triazoles (fluconazole, itraconazole)
Tricyclic antidepressants (amitriptyline, desipramine, doxepin, imipramine, maprotiline)
Trimethadione
Triparanol
Vasopressin
Spironolactone

*Established by multiple reports or proved by rechallenge.
†Hair loss usually severe.
‡May produce permanent alopecia.
§May produce anagen effluvium.
‖May produce telogen effluvium 3 months after discontinuation.
¶May produce androgenetic alopecia.

other body hairs are less commonly involved. Hair shedding usually starts 4 to 6 weeks after drug intake and may be very severe, with up to 1000 hairs shed daily. Regrowth of hair is usually fast after discontinuation of therapy, but hair shape and color may be different. Permanent alopecia may occur with high dose radiation and certain drug regimens, such as busulphan. Scalp hypothermia may prevent or reduce hair loss during chemotherapy.■ Topical minoxidil accelerates hair regrowth but does not prevent hair loss.

Patterned Alopecia (Androgenetic Alopecia)

Androgenetic alopecia, which is the most common form of hair loss, affects up to 80% of men and 50% of women in the course of their life. Androgenetic alopecia is caused by a progressive reduction in the diameter, length, and pigmentation of the hair. Hair thinning is not diffuse, but rather is limited to the frontal, temporal, and vertex areas, where hair follicles are sensitive to the effects of the testosterone metabolite, dehydrotestosterone (DHT). This sensitivity to DHT, which requires the 5-α-reductase enzymes, is genetically determined. In male pattern hair loss, androgenetic alopecia involves the frontotemporal areas and the vertex, following a pattern that corresponds to the Hamilton-Norwood scale. In female pattern alopecia, androgenetic alopecia produces diffuse thinning of the crown region with maintenance of the frontal hairline (Ludwig pattern), a pattern that can easily be appreciated by making a central parting and comparing hair density at the top with hair density at the occipital region. Severe female pattern alopecia also often involves parietal and occipital regions with diffuse thinning. In premenopausal women, androgenetic alopecia can be a sign of hyperandrogenism, together with hirsutism and acne. In most women, however, androgenetic alopecia occurs in the absence of biochemical and clinical evidence of androgen excess and may be due to excessive follicular sensitivity to androgens.

Androgenetic alopecia is a progressive disease that tends to worsen with time. Medical treatments of androgenetic alopecia include 2% topical minoxidil in women and 5% topical minoxidil■ or oral finasteride, 1 mg daily, in men.■ Clinical improvement is mostly due to thickening of the preexisting hair.

Treatments for androgenetic alopecia should be continued for at least 6 months before assessing their efficacy, and regular drug use is mandatory for maintaining results. Interruption of minoxidil produces an acute telogen effluvium, which becomes evident 3 to 4 months often interruption and cannot be prevented by concomitant finasteride treatment. Interruption of finasteride is followed by gradual hair loss with return to the pretreatment status after 1 year. Hair transplantation is a good option for men with severe androgenetic alopecia, and treatment with finasteride, 1 mg daily, improves the long-term results of surgery. Hair transplantation in women is more complicated because the hair thinning is often diffuse in the parietal and occipital regions, so there is not a good hair donor area. In addition, surgery may induce an effluvium of the preexisting hair in the recipient area, which, in women, produces significant temporary worsening of the hair thinning.

PATCHY ALOPECIA

Alopecia Areata

Alopecia areata is a common form of nonscarring, usually patchy hair loss affecting up to 2% of the population. The etiology is unknown, but evidence is consistent with an autoimmune disease, to which both a genetic predisposition and environmental factors contribute. In genetically predisposed individuals, various triggering factors cause a predominantly CD8-driven, T_H1-type T-cell autoimmune reaction against the hair follicles, thereby resulting in acute hair loss.

The disease occurs in all ethnic groups and in both sexes. It can start at any age, but severe forms often start during childhood and are more frequent in males. Clinical examination reveals one or multiple well-circumscribed smooth patches of nonscarring absence of hair that enlarge in a centrifugal way (Fig. 450-1). The margins of the patches often are composed of hair 3 mm in length with a broken pigmented tip (exclamation mark hairs), which indicates that the disease is progressing.

Alopecia areata may affect all hairy body areas. Severe forms involve the entire scalp (alopecia areata totalis) or all body hair (alopecia areata universalis). Involvement of the scalp margins (ophiasis) is associated with a poor prognosis. Alopecia areata may be associated with other autoimmune diseases, most commonly thyroid diseases (Chapter 233). Other possible associations include celiac disease (Chapter 142), vitiligo (Chapter 449), and atopy (Chapter 446). Nail abnormalities are common, especially in children.

The natural history of alopecia areata is unpredictable. Studies indicate that 34 to 50% of patients will recover within 1 year and 15 to 25% will progress to total loss of scalp hair or loss of hair from the entire scalp and body, a condition for which full recovery is only about 10%. To date, there is no cure for alopecia areata, and available treatments may induce temporary hair regrowth but do not change the long-term prognosis.■

Relapses often occur in a high percentage of patients, even during therapy. High-dose pulse corticosteroid therapy is effective in about 60% of patients with acute alopecia areata but is not useful in ophiasis or long-standing alopecia totalis or alopecia universalis. Intralesional steroids can be used in localized forms of alopecia, including alopecia areata of the eyebrows. High-potency topical steroids (clobetasol propionate cream 0.05%) under occlusion induce regrowth in about 25% of patients with long-standing alopecia totalis or alopecia universalis, but relapses are common. Clobetasol propionate 0.05% in foam can be used in patchy alopecia areata. Topical immunotherapy with diphenylcyclopropenone (DPCP) or squaric acid dibutylester (SADBE), which is used in Europe but is not approved by the U.S. Food and Drug Administration, induces hair regrowth in about 20% of patients with severe alopecia totalis or alopecia universalis. Medium- and low-potency topical steroids and topical minoxidil are probably only placebo treatments for alopecia areata.

Trichotillomania

Trichotillomania is a compulsive disorder that is more common in children. Repetitive hair pulling and plucking produces patches of irregular alopecia. The scalp is not completely bald, but rather shows broken hairs of various

FIGURE 450-1. Alopecia areata: patchy hair loss. The alopecic area is devoid of hairs, and the scalp does not present inflammatory changes.

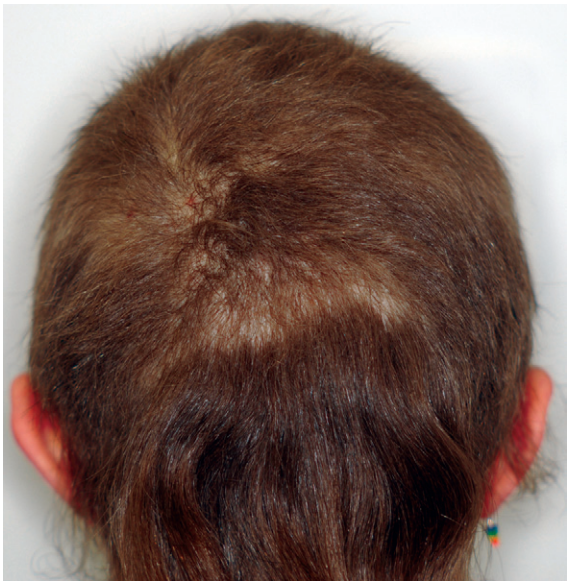

FIGURE 450-2. Trichotillomania: patchy hair loss. The alopecic area has an irregular shape and present hairs broken at different lengths. Also note scalp excoriations.

lengths (Fig. 450-2). The frontal, parietal, and occipital scalp are most commonly affected, but other terminal hairs can be involved, especially the upper eyelashes.

Occasionally, patients develop the habit of chewing or eating the pulled hairs. Patients with trichotillomania frequently do not admit their habit, and parents of affected children may be recalcitrant to accept the diagnosis. Psychiatric referral may be indicated, especially in adults.

Cicatricial Alopecias (Scarring Alopecia)

The hallmark of cicatricial alopecias is loss of follicular ostia. Cicatricial alopecias include diseases that primarily affect the hair follicles as well as diseases that affect the dermis and secondarily cause follicular destruction. In cicatricial alopecia, the scalp has atrophic bald areas that may slowly enlarge centrifugally. The differential diagnosis among the different diseases (e.g., lichen planopilaris, discoid lupus erythematosus, folliculitis decalvans) that cause cicatricial alopecia requires the evaluation of pathologic specimens because clinical features are usually not diagnostic. The biopsy should be taken from scalp areas that show active evidence of inflammation because biopsy of atrophic scalp will typically show only follicular or dermal fibrosis.

LICHEN PLANOPILARIS

In lichen planopilaris, which is the most common form of cicatricial alopecia, the hair follicles surrounding the alopecic patches show perifollicular erythema and follicular plugging. The patient usually complains of severe itching. A variant of lichen planopilaris is frontal fibrosing alopecia, which typically affects the frontal hairline of postmenopausal women with a bandlike scarring

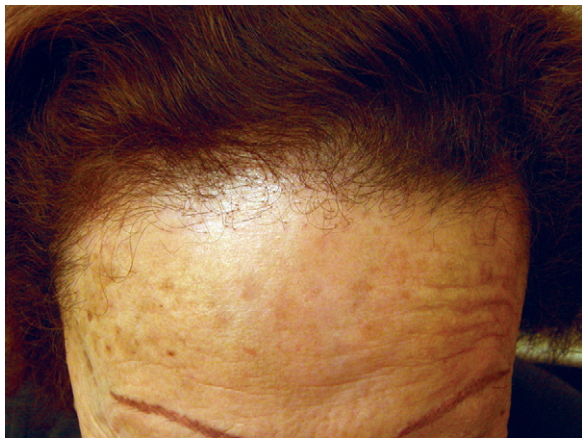

FIGURE 450-3. Frontal fibrosing alopecia. Scarring alopecia of the hair margin with recession of the frontal hairline.

alopecia, often associated with marked decrease or complete loss of the eyebrows (Fig. 450-3). The pathogenesis is unknown, but lichen planopilaris may be a hair-specific autoimmune reaction, in which T lymphocytes target follicular antigens located mainly in the bulge area, with relative sparing of the interfollicular dermis. No consistently effective treatment for lichen planopilaris is available, but attempted treatments include intralesional or systemic steroids, oral tetracyclines, and systemic antimalarials.

DISCOID LUPUS ERYTHEMATOSUS

In discoid lupus erythematosus, the alopecic area shows active inflammation with erythema, edema, scaling, and follicular plugging, as well as atrophy with variable degrees of telangiectasia and dyspigmentation.

Females are more often affected, and the disease is more common in African American women. Approximately 5 to 10% of adults with discoid lupus erythematosus will develop systemic lupus erythematosus (Chapter 274), especially those with widespread discoid lesions. In localized lesions, treatment with high-potency topical steroids (see Table 445-1 in Chapter 445) is usually effective. Antimalarials are a second-line treatment. Hair regrowth may occur when treatment is promptly started. Therapeutic strategy should include photoprotection of the involved area.

FOLLICULITIS DECALVANS

In folliculitis decalvans, the scalp shows papulopustular lesions that often coalesce to form exudative crusted areas that result in cicatricial alopecia. A frequent clinical finding is tufted folliculitis, that is, tufts of 5 to15 hairs that emerge together from the scalp. The cause is unknown, but the condition may reflect an abnormal host response to bacterial antigens. *Staphylococcus aureus* is often isolated from active lesions. Folliculitis decalvans sometimes responds to oral antibiotics (e.g., trimethoprim-sulfamethoxazole or clindamycin with or without rifampin for 8 to 10 weeks) but usually relapses after interruption of therapy. The disease tends to have a prolonged course with frequent inflammatory relapses and, sometimes, severe scarring.

HAIR DISORDERS IN CHILDREN

Hereditary and congenital alopecias are present since birth or appear in the first years of life. Aplasia cutis congenita is the most common form of focal alopecia in newborns. Patterned hair loss in a prepubertal child does not exclude the diagnosis of androgenetic alopecia because the disease may appear at the time of pubarche in the absence of any endocrinologic abnormality.

Hereditary hair shaft abnormalities associated with increased hair fragility produce diffuse or patchy alopecia that appears during childhood. The most common hereditary hair shaft disorder is monilethrix, in which hair shaft fragility is associated with follicular hyperkeratosis. The hair is dull and fragile and breaks easily, especially in the nape and occipital areas. Diagnosis is confirmed by finding hair beading on microscopic examination of the hair shaft.

Congenital triangular alopecia is usually noticed by the age of 6 years as an irregularly triangular patch of alopecia on the frontotemporal region. The presence of vellus hairs in the area is diagnostic and suggests a possible nevoid origin of the alopecia.

The loose anagen hair syndrome is characterized by a defective anchorage of the hair to the follicle, thereby resulting in hairs that are easily and painlessly pulled out from the scalp. The condition is typical of children and may manifest with patchy hair loss due to hair pulling while playing.

RACIAL DIFFERENCES

The frequency and clinical aspects of hair disorders vary in different races. Androgenetic alopecia, for instance, is more frequent in whites than in blacks and Asians, whereas black and Asian hair is more susceptible to weathering and fragility.

The black hair shaft is flat in shape, highly twisted, and difficult to manage without strong chemical or hair styling procedures, which often cause considerable damage to the hair. Hair straightening and braiding are responsible for traction alopecia, which is common and typically produces cicatricial alopecia of the frontal and lateral margins.

In Asians, the hair shaft is round in shape, thick, robust, and straight. Asian hair is very difficult to style and dye, and it is often damaged by its treatment with high concentrations or long exposure to chemicals.

EXCESSIVE HAIR GROWTH

Hirsutism describes excessive terminal hair with male distribution in a female. Hirsutism should be distinguished from hypertrichosis, which is characterized by the presence of an excessive amount of hair in a non–androgen-dependent area.

Hirsutism

Hirsutism is a common condition that affects up to 10% of women. The prevalence of hirsutism is influenced by genetic and racial factors. It is more frequent in Hispanic and Mediterranean women than in Asian or African women. Hirsutism may or not be associated with hyperandrogenism or with acne and androgenetic alopecia. Idiopathic hirsutism accounts for about 15% of cases.

Hypertrichosis

Hypertrichosis results from the presence of terminal hairs in anatomic areas that are normally characterized by vellus hair. Hypertrichoses can be congenital or acquired, localized or generalized. Acquired hypertrichoses are most commonly iatrogenic, metabolic (e.g., Cushing's syndrome, porphyria, hyperthyroidism), nutritional (e.g., anorexia nervosa), or paraneoplastic (Chapter 187).

NAIL DISORDERS

Normal Nail

The nail plate is a keratinized hard structure produced by the nail matrix, which is a specialized epithelium located above the distal phalanx of the finger. In longitudinal sections, the matrix consists of a dorsal, an apical, and a ventral portion. The proximal matrix (dorsal portion and apex) produces the dorsal nail plate (two thirds upper plate), and the distal matrix (ventral portion) produces the ventral plate (one third lower plate). The nail plate is produced continuously throughout life. Nails grow slowly, and the nail plate can reflect illnesses that occurred several months before nail abnormality is evident. Complete replacement takes about 6 months for a fingernail and 12 to 18 months for a toenail. Many medications (e.g., anticonvulsants, neuroleptics, antifungals), drugs (e.g., amphetamine, cocaine, doping substances), and poisons (e.g., mercury, arsenic) are retained in the nails, whose fragments (nail clippings) can be used to monitor previous exposure.

NAIL DISORDERS

Nail abnormalities can be congenital or acquired and may caused by developmental, traumatic, inflammatory, infective, and neoplastic disorders or by medications. The diagnosis of nail dystrophies usually relies on a careful clinical examination and an accurate history, but radiographic or magnetic resonance imaging investigation of the digit and pathology may be required.

Koilonychia (Spoon Nails)

In koilonychia (Fig. 450-4), which is also called spooning of the nails, the nail plate is thin and has a concave appearance. Koilonychia is physiologic in children. In adults, it can be occupational or, more rarely, a sign of iron deficiency (Chapter 162).

Clubbing

Clubbing (Fig. 450-5) develops when enlargement of the soft tissue of the distal digit causes a bulbous digit with an enlarged and overcurved nail plate. The angle between the proximal nail fold and the nail plate (Lovibond's angle) is greater than 180 degrees. Clubbing may be congenital (i.e., in congenital heart disease; Chapter 69) or acquired. Other causes of acquired clubbing include intrathoracic and gastrointestinal neoplasms (Chapter 187), chronic intrathoracic suppurative disease (Chapter 90), inflammatory bowel disease (Chapter 143), and liver disorders.

FIGURE 450-4. Spooning. (Available at McGraw-Hill's Access Medicine: http://www.accessmedicine.com/search/searchAMResultImg.aspx?rootterm=koilonychia&rootID=41210&searchType=1.)

FIGURE 450-5. Clubbing. (Available at The Dermatologists' Image Resource: http://www.dermnet.com/image.cfm?passedArrayIndex=3&moduleID=13&moduleGroupID=183. Accessed May 24, 2006.)

Beau's Lines and Onychomadesis

Beau's lines (Fig. 450-6) and onychomadesis are due to a temporary reduction or arrest of the mitotic activity of the proximal matrix. Beau's lines appear as transverse grooves of various depth; onychomadesis as a full-thickness transverse groove of the proximal nail plate. Causes (Table 450-3) include trauma, skin diseases involving the proximal nail fold and the matrix, and systemic diseases. In the latter case, Beau's lines or onychomadesis involve all the nails and are localized at the same level.

Pitting

Pitting (Fig. 450-7) appears as punctate depressions of the dorsal nail plate, with variable breadth and depth. Pitting is caused by inflammatory skin disorders such as psoriasis (Chapter 446), alopecia areata, and eczema (Chapter 446).

Longitudinal Grooves and Striations

Normal nails often show superficial thin longitudinal ridges that increase in number with aging. Deep longitudinal fissures, which indicate damage to the proximal matrix, can be caused by nail lichen planus, vascular insufficiency, trauma, and tumors involving or compressing the matrix.

Leukonychia

Leukonychia describes a whitish discoloration of the nail, which may be due to persistence of nuclei in the cells of the ventral nail plate (true leukonychia), or to a pallor of the nail bed (apparent leukonychia). True leukonychia does not fade with pressure and moves distally with nail growth; it is most commonly caused by trauma. Apparent leukonychia, which does not follow nail

FIGURE 450-6. Beau's lines after a severe infection. The lines affect all the nails at the same level.

TABLE 450-3 CAUSES OF BEAU'S LINES AND ONYCHOMADESIS

SYSTEMIC
Acrodermatitis enteropathica
Severe metabolic stress
High fever
Viral infections (Kawasaki disease, measles, hand-foot-and-mouth syndrome)
Typhus
Stevens-Johnson syndrome
Drugs
Bullous disorders (pemphigus, pemphigoids)
Deep saturation, high altitude
Hemodialysis
Myocardial infarction
LOCAL
Trauma (including manicure)
Paronychia
Congenital malalignment (big toenails)

growth and fades with pressure, may be a sign of systemic diseases such as liver cirrhosis (Terry's nails; Chapter 148), chronic renal diseases (half-and-half nails, characterized by apparent leukonychia of the proximal half of the nail; Chapter 132), hypoalbuminemia (Chapter 123), and systemic chemotherapy (Muehrcke's lines; Fig. 450-8).

Yellow Nail Syndrome

The yellow nail syndrome is a chronic nail disorder characterized by an arrest or a reduction of nail growth, resulting in nail thickening, hardening, and yellow discoloration. Fingernails and toenails are excessively curved from side to side, and cuticles are absent (Fig. 450-9). Yellow nail syndrome may occasionally be paraneoplastic (Chapter 187). The pathogenesis of yellow nail syndrome is unknown, but a congenital abnormality of the lymphatic vessels may be involved. Typical cases have associated lymphedema or respiratory disturbances. The nail abnormalities improve with treatment of the associated respiratory disorders. Oral Vitamin E (1200 mg/day for several months) is useful in some cases.

Splinter Hemorrhages

Splinter hemorrhages (see Fig. 50-11 in Chapter 50) appear as longitudinal thin red-brown lines of variable length. Splinter hemorrhages are usually localized in the distal nail and are commonly seen in inflammatory diseases, including eczema (Chapter 446), psoriasis (Chapter 446), and onychomycosis. Multiple splinter hemorrhages localized in the proximal nail plate can be a sign of systemic diseases, including infectious or marantic endocarditis (Chapter 76), trichinosis (Chapter 365), and the antiphospholipid syndrome.

Onycholysis

Onycholysis (Fig. 450-10) describes detachment of the nail plate from the bed. The detachment usually occurs at the free lateral margins of the nail. The

FIGURE 450-7. Pitting and onycholysis in nail psoriasis.

FIGURE 450-8. Muehrcke's lines. (From Wikipedia Commons.)

FIGURE 450-9. Yellow nail syndrome. The nails are yellow, overcurved, and thickened and do not grow.

onycholytic area is white owing to the presence of air, but it may acquire a green-brown color if the space if colonized by bacteria, such as *Pseudomonas aeruginosa*.

Onycholysis of the fingernails is a common sign of nail psoriasis (Chapter 446). It may also be due to prolonged and frequent contact with water, detergents, or irritants (idiopathic onycholysis). Toenail onycholysis is almost exclusively caused by trauma or onychomycosis. When onycholysis is limited to one digit, the possibility of a nail tumor should always be considered.

Paronychia

Paronychia, which describes the acute or chronic inflammation of the proximal and lateral nail folds, is common in the fingernails at any age. In acute paronychia, the affected digit is painful, with erythema, swelling, and pus discharge localized to one corner of the proximal nail fold. Acute paronychia usually follows a trauma to the nail fold, as in children who pick or bite the cuticles or in women after a manicure. Treatment with mild-potency topical steroids (see Table 445-1 in Chapter 445) and antibiotics (e.g., amoxicillin and clavulanic acid, 1 mg per day for 5 days in adults) promptly induces regression of the condition.

FIGURE 450-10. Onycholysis. Note the detachment of the distal nail from the nail bed. (From Dartmouth University and Dermnet Weekly Clinic, July 30, 2001.)

In chronic paronychia, prolonged mechanical or environmental trauma (such as contact with water and irritants) damages the cuticle, allowing penetration of dirt, bacteria, and other particles under the proximal nail fold. The result is an inflammatory reaction of the proximal nail fold and nail matrix, with edema and redness of the fold, absence of the cuticles, Beau's lines, and abnormalities of the nail plate surface. Treatment includes protective measures, such as use of cotton and rubber gloves to avoid contact with irritants, as well as topical steroids and topical antimicrobials.

Onychomycosis

Fungal nail infections most commonly affect the toenails of adults. Dermatophytes (particularly *Trichophyton rubrum*) are responsible for most infections. The clinical presentation varies depending on the modality of the nail invasion. In distal subungual onychomycosis, which is the most common form, fungi spread from plantar skin and invade the nail bed. The affected nail shows subungual hyperkeratosis, onycholysis, and yellow streaks. In white superficial onychomycosis, which only affects toenails, fungi colonize the surface of the nail plate, where they cause multiple white friable patches. Proximal subungual onychomycosis produces a true leukonychia, owing to the presence of fungal hyphae in the deep layers of the plate. Proximal subungual onychomycosis caused by *T. rubrum* is typical in immunosuppressed patients. Treatment of onychomycosis depends on the clinical type, the number of affected nails, and severity of nail involvement. A systemic treatment is always required for proximal subungual onychomycosis and for distal subungual onychomycosis involving the proximal nail. Terbinafine (250 mg per day) for 2 (fingernails) or 3 (toenails) months is the most effective treatment for dermatophyte infections.[5]

Ingrowing Toenails

Ingrown toenails are a common condition, especially in young patients. Nail ingrowing most commonly affects one or both the big toes and is related to genetic factors, hyperhidrosis, and poorly fitting shoes. Ingrowing is usually precipitated by incorrect nail trimming, with formation of a sharp edge (spicule) of the lateral nail plate that penetrates and injures the soft tissues of the lateral nail fold. Depending on severity, treatment varies from simple disembedding of the spicule to chemical destruction of the lateral nail matrix by phenolization.[6]

Nail Pigmentation

Nail pigmentation is usually caused by staining from external agents, such as nicotine or hair dyes. It may rarely be due to drugs deposition in the nail plate or into the nail bed (i.e., antimalarials) or systemic diseases (argyria). In these cases, the proximal margin of the pigmentation follows the shape of the lunula.

Melanonychia

Melanonychia is defined by the presence of melanin within the nail plate. It appears more often as a longitudinal brown-black band starting from the matrix and extending to the free edge of the nail plate. Less often, the pigmentation can involve the whole nail plate or present as a transverse band.

Melanonychia results from production of melanin by melanocytes of the nail matrix, where melanocytes are usually quiescent but may become active and start melanin synthesis. Melanonychia has three main causes: simple melanocytic activation, benign melanocyte proliferations (lentigo, nevus), and malignant melanocyte proliferation (melanoma; Chapter 210).

Common causes of longitudinal melanonychia due to melanocytic activation include inflammatory and traumatic nail disorders, drugs (chemotherapy, azidothymidine, antimalarials, PUVA therapy) (Fig. 450-11), and systemic diseases (acquired immunodeficiency syndrome [Chapter 399]; Addison's disease [Chapter 234]).

FIGURE 450-11. Melanonychia and apparent leukonychia (Muehrcke's lines) in a patient undergoing systemic chemotherapy with cisplatin.

FIGURE 450-12. Nail melanoma. Melanonychia and periungual pigmentation (Hutchinson's sign).

Nail melanoma is rare and most frequently involves the thumb of middle-aged individuals. Diagnosis is often delayed, and the 5-year survival is only 15%. Hutchinson's sign, extension of the pigmentation to the proximal or lateral nail folds, is an important indicator of nail melanoma (Fig. 450-12).

APPENDIX

REFERENCE INTERVALS AND LABORATORY VALUES*

RONALD J. ELIN

Reference intervals are valuable guidelines for the clinician to assess health and disease, but they should not be used as absolute indicators of health and disease. For essentially every test, significant overlap exists between healthy and diseased populations. Many factors may influence the determination of the reference interval. The method and mode of standardization are variables for the reference interval, particularly for immunologic and enzymatic tests. The selection of the "normal" population is also important because factors such as age, gender, race, diet, personal habits (e.g., alcohol consumption, smoking), and exercise may influence the reference interval for a given analyte. Finally, the statistics chosen to define the reference interval are also a factor. These multiple variables for determining the reference interval indicate why differences exist among institutions for the same analyte.

The values in this chapter are primarily for adults in the fasting state. Values for other groups, when included, are clearly identified. Prefixes and abbreviations are listed in Table Appendix-1. For convenience, this chapter is divided into the following three sections: clinical chemistry, toxicology, and serology (Table Appendix-2); hematology and coagulation (Table Appendix-3); and drugs; therapeutic and toxic (Table Appendix-4). The list includes reference intervals for the most common tests used in the practice of internal medicine.

All laboratory values are given in conventional and international units. If the value and units for a reference interval are the same for conventional and international units, the interval is listed only in the column for international units. The temperature for all enzyme assays listed in the chapter is 37° C. The pertinent prefixes denoting the decimal factors and abbreviations are listed in Table Appendix-1.

*The material in this chapter was partially extracted from Tietz NW, ed. *Clinical Guide to Laboratory Tests*. Philadelphia: WB Saunders; 1995. The material for the section on therapeutic drug concentrations was partially extracted from Burtis CA, Ashwood ER, eds. *Tietz Textbook of Clinical Chemistry*. Philadelphia: WB Saunders; 1994. The main contributors to this section of the book are P. C. Painter, J. Y. Cope, and J. L. Smith.

TABLE APPENDIX-1 PREFIXES AND ABBREVIATIONS

Prefixes Denoting Decimal Factors

PREFIX	SYMBOL	FACTOR
mega	M	10^{6}
kilo	k	10^{3}
hecto	h	10^{2}
deca	da	10^{1}
deci	d	10^{-1}
centi	c	10^{-2}
milli	m	10^{-3}
micro	μ	10^{-6}
nano	n	10^{-9}
pico	p	10^{-12}
femto	f	10^{-15}

ABBREVIATIONS	
AU	Arbitrary units
CSF	Cerebrospinal fluid
EDTA	Ethylenediaminetetraacetic acid
EU	Ehrlich unit
GD	General diagnostics
Hb	Hemoglobin
hpf	High-power field
IFA	Immunofluorescence assay
IU	International unit (of hormone activity)
Kat	Katal
Pa	Pascal
RBC	Red blood cell
RIA	Radioimmunoassay
RID	Radial immunodiffusion
S	Substrate
U	International unit (of enzyme activity)
WBC	White blood cell

TABLE APPENDIX-2 CLINICAL CHEMISTRY, TOXICOLOGY, AND SEROLOGY

TEST	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)	REFERENCE INTERVAL (INTERNATIONAL UNITS)
Acetoacetate Semiquantitative	Serum or plasma (fluoride/oxalate)	Negative (<1 mg/dL)	Negative (<0.1 mmol/L)

Glucose	Serum	Adult: 74-106 mg/dL >60 yr: 80-115 mg/dL	4.1-5.9 mmol/L 4.4-6.4 mmol/L
	Whole blood (heparin)	65-95 mg/dL	3.6-5.3 mmol/L
	CSF	40-70 mg/dL	2.2-3.9 mmol/L
Quantitative, enzymatic	Urine	<0.5 g/day	<2.8 mmol/day
Qualitative	Urine		Negative
Glucose, 2-hr postprandial	Serum	<126 mg/dL	<7.0 mmol/L
Glucose, tolerance test (GTT), oral	Serum	mg/dL *Normal* / *Diabetic* Fasting: 70-105 / >140 60 min: 120-170 / ≥200 90 min: 100-140 / ≥200 120 min: 70-120 / ≥140	mmol/L *Normal* / *Diabetic* 3.9-5.8 / >7.8 6.7-9.4 / ≥11 5.6-7.8 / ≥11 3.9-6.7 / ≥7.8
γ-Glutamyltransferase (GGT) (Szasz method)	Serum	M: 2-30 U/L F: 1-24 U/L	0.03-0.51 µKat/L 0.02-0.41 µKat/L

TABLE APPENDIX-2 CLINICAL CHEMISTRY, TOXICOLOGY, SEROLOGY—cont'd

TEST	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)	REFERENCE INTERVAL (INTERNATIONAL UNITS)
Growth hormone (hGH, somatotropin)	Serum	Adult, M: 0-4 ng/mL F: 0-18 ng/mL >60 yr, M: 1-9 ng/mL F: 1-16 ng/mL	0-4 µg/L 0-18 µg/L 1-9 µg/L 1-16 µg/L
Haptoglobin (see Table Appendix-3)			
HDL cholesterol (HDLC) (5th percentile from Lipid Research Clinics)	Serum or plasma (EDTA)	M: >29 mg/dL F: >35 mg/dL	>0.75 mmol/L >0.91 mmol/L
Hemoglobin A_{1c} (electrophoresis)	Whole blood (heparin, EDTA, or oxalate)	4.0-6.0% of total Hb	Fraction of Hb: 0.040-0.060
Homovanillic acid (HVA)	Urine, 24-hr	1.4-8.8 mg/day	8-48 µmol/day
17-Hydroxycorticosteroids (17-OHCS)	Urine, 24-hr	M: 3.0-10.0 mg/day F: 2.0-8.0 mg/day	8.3-27.6 µmol/day 5.5-22.1 µmol/day
5-Hydroxyindole acetic acid (5-HIAA) Qualitative Quantitative	 Urine, fresh random Urine, 24-hr	 2-6 mg/day	 Negative 10.4-31.2 µmol/day
17-Hydroxyprogesterone (17-OHP)	Serum	M: 0.5-2.5 ng/mL F: Follicular: 0.2-1.0 ng/mL Luteal: 1.-5.0 ng/mL Postmenopausal: ≤0.7 ng/mL	1.5-7.5 nmol/L 0.6-3.0 nmol/L 3.0-15.5 nmol/L ≤2.1 nmol/L
Immunoglobulin A (IgA)	Serum	40-350 mg/dL	400-3500 mg/L
Immunoglobulin D (IgD)	Serum	0-8 mg/dL	0-80 mg/L
Immunoglobulin E (IgE)	Serum	0-380 IU/mL	0-380 kIU/L
Immunoglobulin G (IgG)	Serum CSF	650-1600 mg/dL 0.5-5 mg/dL	6.5-16 g/L 5-50 mg/L
Immunoglobulin M (IgM)	Serum	55-300 mg/dL	550-3000 mg/L
Insulin (12-hr fasting), immunoreactive	Serum	0.7-9.0 µIU/mL	5-63 pmol/L
Intrinsic factor (see Vitamin B_{12})			
Iron	Serum	M: 65-175 µg/dL F: 50-170 µg/dL	11.6-31.3 µmol/L 9.0-30.4 µmol/L
Iron-binding capacity, total (TIBC)	Serum	250-450 µg/dL	44.8-80.6 µmol/L
Iron saturation	Serum	 M: 20-50 F: 15-50	Fraction of iron saturation: 0.20-0.5 0.15-0.5
17-Ketogenic steroids (17-KGS)	Urine, 24-hr	M: 5-23 mg/day F: 3-15 mg/day	17-80 µmol/day 10-52 µmol/day
Ketone bodies Qualitative	Serum Urine, random	Negative (0.5-3.0 mg/dL)	Negative (5-30 mg/L) Negative
17-Ketosteroids, total (17-KS)	Urine, 24-hr	M: 10-25 mg/day F: 6-15 mg/day	37-87 µmol/day 21-52 µmol/day
L-Lactate	Whole blood (heparin)	Venous: 8.1-15.3 mg/dL Arterial: <11.3 mg/dL	0.9-1.7 mmol/L <1.3 mmol/L
Lactate dehydrogenase (LDH)	Serum		208-378 U/L
Lead	Whole blood (heparin) Urine	<25 µg/dL Toxic: ≥100 µg/dL <80 µg/dL	<1.21 µmol/L ≥4.83 µmol/L <0.39 µmol/L
Light chains, free Kappa Lambda K/L ratio	Serum 	 0.33-1.94 mg/dL 0.571-2.63 mg/dL	 3.3-19.4 mg/L 5.71-26.3 mg/L 0.26-1.65
Lipase	Serum	31-186 U/L	0.5-3.2 µKat/L
Low-density-lipoprotein cholesterol (LDLC)	Serum or plasma (EDTA)	Recommended: <130 mg/dL Moderate risk: 130-159 mg/dL High risk: ≥160 mg/dL	<3.37 mmol/L 3.37-4.12 mmol/L ≥4.14 mmol/L
Lutropin (LH)	Serum or plasma (heparin) Urine	M: 1-8 mU/mL F: Follicular phase: 1-2 mU/mL Midcycle: 16-104 mU/mL Luteal: 1-12 mU/mL Postmenopausal: 16-66 mU/mL	1-8 U/L 1-12 U/L 16-104 U/L 1-12 U/L 16-66 U/L M: 9-23 U/day F: non-midcycle, 4-30 U/day

TABLE APPENDIX-2 CLINICAL CHEMISTRY, TOXICOLOGY, SEROLOGY—cont'd

TEST	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)	REFERENCE INTERVAL (INTERNATIONAL UNITS)
Lysozyme	Serum, plasma	0.4-1.3 mg/dL	4-13 mg/L
Magnesium	Serum Urine, 24-hr	1.3-2.1 mEq/L 6.0-10.0 mEq/day	0.65-1.05 mmol/L 3.00-5.00 mmol/day
Mercury	Whole blood (EDTA) Urine, 24-hr	<5.0 µg/dL <20 µg/L Toxic: >150 µg/L	<0.25 µmol/L <0.1 µmol/L <0.75 µmol/L
Metanephrine, total	Urine, 24-hr	0.05-1.20 µg/mg creatinine	0.03-0.69 mmol/mol creatinine
Myelin basic protein	CSF		<2.5 µg/L
Myoglobin	Serum Urine, random		M: 19-92 µg/L F: 12-76 µg/L Negative
Osmolality	Serum Urine, random Urine, 24-hr		275-295 mOsmol/kg 50-1200 mOsmol/kg, depending on fluid intake After 12-hr fluid restriction: >850 mOsmol/kg ~390-900 mOsmol/kg
Oxalate	Serum	1-2.4 µg/mL Ethylene glycol poisoning: >20 µg/mL	11-27 µmol/L Ethylene glycol poisoning: >228 µmol/L
Oxygen (P_{O_2})	Whole blood, arterial (heparin)	83-108 mm Hg	11-14.4 kPa
Oxygen saturation	Whole blood, arterial (heparin)	95-98%	Fraction saturated: 0.95-0.98
Parathyroid hormone	Serum	Varies with laboratory N-terminal 8-24 pg/mL C-terminal 50-330 pg/mL Intact 10-65 pg/mL	 8-24 ng/L 50-330 ng/L 10-65 ng/L
pH (37° C)	Whole blood, arterial (heparin)		7.35-7.45
Phosphorus, inorganic	Serum Urine, 24-hr	2.7-4.5 mg/dL >60 yr, M: 2.3-3.7 mg/dL F: 2.8-4.1 mg/dL 0.4-1.3 g/day	0.87-1.45 nmol/L 0.74-1.2 nmol/L 0.90-1.3 nmol/L 13-42 mmol/d
Porphobilinogen (PBG) Quantitative Qualitative	 Urine, 24-hr Urine, fresh random	 0-2.0 mg/day	 0-8.8 µmol/d Negative
Potassium	Serum Plasma (heparin) Urine, 24-hr	3.5-5.1 mEq/L 3.5-4.5 mEq/L 25-125 mEq/day	3.5-5.1 mmol/L 3.5-4.5 mmol/L 25-125 mmol/day
Pregnanediol	Urine, 24-hr	M: 0-1.9 mg/day F: Follicular: <2.6 mg/day Luteal: 2.6-10.6 mg/day Postmenopausal: 0.2-1.0 mg/day	0-5.9 µmol/day <8 µmol/day 8-33 µmol/day 0.6-3.1 µmol/day
Progesterone	Serum	M: 0.13-0.97 ng/mL F: Follicular: 0.15-0.70 ng/mL Luteal: 2.0-25 ng/mL	0.4-3.1 nmol/L 0.5-2.2 nmol/L 6.4-79.5 nmol/L
Prolactin (hPRL)	Serum	M: 3.0-14.7 ng/mL F: 3.8-23.2 ng/mL	3.0-14.7 µg/L 3.8-23.2 µg/L
Prostate-specific antigen (PSA)	Serum, freeze	M: <4 ng/mL	<4 µg/L
Protein Total Electrophoresis (cellulose acetate) Total Total	 Serum Serum Urine, 24-hr CSF	 6.4-8.3 g/dL Albumin: 3.5-5.0 g/dL α_1-Globulin: 0.1-0.3 g/dL α_2-Globulin: 0.6-1.0 g/dL β-Globulin: 0.7-1.1 g/dL γ-Globulin: 0.8-1.6 g/dL Lumbar: 15-45 mg/dL	 64.0-83.0 g/L 35-50 g/L 1-3 g/L 6-10 g/L 7-11 g/L 8-16 g/L 50-80 mg/day at rest 150-450 mg/L
Pyruvic acid	Whole blood (heparin)	0.3-0.9 mg/dL	0.03-0.10 mmol/L
Renin (normal diet)	Plasma (EDTA)	Supine: 0.2-1.6 ng/mL/hr Standing: 0.7-3.3 ng/mL/hr	0.2-1.6 µg/L/hr 0.7-3.3 µg/L/hr
Riboflavin (see Vitamin B_2)			
Sediment Casts	Urine, fresh, random		Hyaline: occasional (0-1) casts/hpf RBC: not seen WBC: not seen Tubular epithelial: not seen Transitional and squamous epithelial: not seen

TABLE APPENDIX-2 CLINICAL CHEMISTRY, TOXICOLOGY, SEROLOGY—cont'd

TEST	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)	REFERENCE INTERVAL (INTERNATIONAL UNITS)
Sediment Cells			 RBC: 0-2/hpf WBC: M: 0-3/hpf F: 0-5/hpf Epithelial: few Bacteria: Unspun: no organisms/oil immersion field Spun: <20 organisms/hpf
Sodium	Serum or plasma (heparin) Urine, 24-hr	136-146 mEq/L 40-220 mEq/day	136-146 mmol/L 40-220 mmol/day
Specific gravity	Urine, random Urine, 24-hr		1.002-1.030 1.015-1.025
Testosterone, free	Serum	M: 50-210 pg/mL F: 1.0-8.5 pg/mL	174-729 pmol/L 3.5-29.5 pmol/L
Testosterone, total	Serum Urine	M: 280-1100 ng/dL F: 15-70 ng/dL 20-50 yr, M: 50-135 µg/day F: 2-12 µg/day >50 yr, M: 40-60 µg/day F: 2-8 µg/day	9.7-38.2 nmol/L 0.5-2.4 nmol/L 173-470 nmol/day 7-42 nmol/day 139-210 nmol/day 7-28 nmol/day
Thiamine (see Vitamin B_1)	Serum	0.10-0.54 µg/dL	2.9-16.1 nmol/L
Thyroglobulin (Tg)	Serum	3-42 ng/mL	3-42 µg/L
Thyroglobulin antibodies	Serum		<1 : 10
Thyroid microsomal antibodies	Serum		Nondetectable (hemagglutination) or <1 : 10 (IFA)
Thyrotropin (hTSH)	Serum or plasma	0.4-4.2 µU/mL	0.4-4.2 mU/L
Thyrotropin-releasing hormone	Plasma	5-60 pg/mL	5-60 ng/L
Thyroxine, free (FT_4)	Serum	0.8-2.4 ng/dL	10-31 pmol/L
Thyroxine (T_4), total	Serum	M: 4.6-10.5 µg/dL F: 5.5-11.0 µg/dL	59-135 nmol/L 71-142 nmol/L
Thyroxine-binding globulin (TBG)	Serum	15.0-34.0 µg/mL	15.0-34.0 mg/L
Thyroxine index, free	Serum		4.2-13.0
Transcortin	Serum	M: 18.8-25.2 mg/L F: 14.9-22.9 mg/L	323-433 nmol/L 256-393 nmol/L
Transferrin	Serum	200-400 mg/dL >60 yr: 180-380 mg/dL	2.0-4.0 g/L 1.80-3.80 g/L
Transthyretin (prealbumin)	Serum	10-40 mg/dL	100-400 mg/L
Triglycerides (TG)	Serum, after ≥12-hr fast	Recommended: <250 mg/dL	2.83 mmol/L
Tri-iodothyronine, free	Serum	260-480 pg/dL	4.0-7.4 pmol/L
Tri-iodothyronine, total (T_3)	Serum	100-200 ng/dL	1.54-3.08 mmol/L
Tri-iodothyronine resin uptake test (T_3RU)	Serum	24-34%	24-34 AU (arbitrary units)
Troponin-I (cTnI)	Serum	Method dependent	<0.8 µg/L
Troponin-T (cTnT)	Serum	Method dependent	<0.01 µg/L
Urea nitrogen	Serum or plasma Urine	6-20 mg/dL 12-20 g/day	2.1-7.1 mmol/L 0.43-0.71 mol/day
Urea nitrogen/creatinine ratio	Serum		12 : 1-20 : 1
Uric acid (uricase)	Serum Urine, 24-hr	M: 3.5-7.2 mg/dL F: 2.6-6.0 mg/dL 250-750 mg/day	0.21-0.42 mmol/L 0.15-0.35 mmol/L 1.48-4.43 mmol/day
Urinary sediment (see Sediment)			
Urobilinogen	Urine, 2-hr Urine, 24-hr Feces	0.1-0.8 EU 0.5-4.0 EU 75-275 EU/100 g 75-400 EU/day 40-280 mg/day	0.1-0.8 U 0.5-4.0 U 750-2750 U/kg 75-400 U/day 67-473 µmol/day
Uroporphyrin	Urine, 24-hr Feces, 24-hr specimen Erythrocytes (heparin or EDTA)	<50 µg/day 10-40 µg/day	<60 nmol/day 12-48 nmol/day Negative
Vanillylmandelic acid (VMA)	Urine, 24-hr	2-7 mg/day	10.1-35.4 µmol/day
Viscosity	Serum		1.10-1.22 centipoise

TABLE APPENDIX-2 CLINICAL CHEMISTRY, TOXICOLOGY, SEROLOGY—cont'd

TEST	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)	REFERENCE INTERVAL (INTERNATIONAL UNITS)
Vitamin A	Serum	30-80 µg/dL	1.05-2.8 µmol/L
Vitamin B_1 (Thiamine)	Serum	0-2 µg/dL	0-75 nmol/L
Vitamin B_2 (Riboflavin)	Serum	4-24 µg/dL	106-638 nmol/L
Vitamin B_6	Plasma (EDTA)	5-30 ng/mL	20-121 nmol/L
Vitamin B_{12}	Serum	200-835 pg/mL	148-616 pmol/L
Vitamin C	Plasma (oxalate, heparin, or EDTA) Urine, 24-hr	0.5-1.5 mg/dL 5-50 µg/day	28-85 µmol/L 0.67-0.665 µmol/day
Vitamin D_3 , 1,25-dihydroxy	Serum	16-65 pg/mL	42-169 pmol/L
Vitamin D_3, 25-hydroxy	Serum or plasma (heparin)	Summer: 15-80 ng/mL Winter: 14-42 ng/mL	37.4-200 nmol/L 34.9-105 nmol/L
Vitamin E	Serum	5.0-18.0 µg/mL	12-42 µmol/L
Zinc	Serum	70-150 µg/dL	10.7-22.9 µmol/L

TABLE APPENDIX-3 HEMATOLOGY AND COAGULATION

TEST	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)	REFERENCE INTERVAL (INTERNATIONAL UNITS)
Activated partial thromboplastin time (APTT)	Plasma (Na citrate)		25-35 sec
Antithrombin III	Plasma (Na citrate)	85-115% of normal human plasma	0.85-1.15
Bleeding time (BT) Ivy Simplate (G-D)	Blood from skin		Normal: 2-7 min Borderline: 7-11 min 2.75-8 min
Blood volume	Whole blood (heparin)		M: 52-83 mL/kg F: 50-75 mL/kg
Bone marrow	Bone marrow aspirate	% (mean)	Number fraction (mean)
Differential count			
Myeloblasts		0.3-5.0(2.0)	0.003-0.05 (0.02)
Promyelocytes		1.0-8.0 (5.0)	0.01-0.08 (0.05)
Myelocytes:			
Neutrophilic		5.0-19.0 (12.0)	0.05-0.19 (0.12)
Eosinophilic		0.5-3.0 (1.5)	0.005-0.03 (0.015)
Basophilic		0.0-0.5 (0.3)	0.00-0.005 (0.003)
Metamyelocytes		13.0-32.0 (22.0)	0.13-0.32 (0.22)
Polymorphonuclear neutrophils		0.7-3.0 (2.0)	0.007-0.03 (0.02)
Polymorphonuclear eosinophils		0.5-4.0 (2.0)	0.005-0.04 (0.02)
Polymorphonuclear basophils		0.0-0.7 (0.2)	0.0-0.007 (0.002)
Lymphocytes		3.0-17.0 (10.0)	0.03-0.17 (0.10)
Plasma cells		0.0-2.0 (0.4)	0.00-0.02 (0.004)
Monocytes		0.5-5.0 (2.0)	0.005-0.05 (0.02)
Reticulum cells		0.1-2.0 (0.2)	0.001-0.02 (0.002)
Megakaryocytes		0.3-3.0 (1.0)	0.003-0.03 (0.01)
Pronormoblasts		1.0-8.0 (4.0)	0.01-0.08 (0.04)
Normoblasts		7.0-32.0 (18.0)	0.07-0.32 (0.18)
Clot lysis, 37° C	Whole clotted blood		47-72 hr
Clot retraction screen	Whole blood (no anticoagulant)		Retraction begins at 1 hr maximum at 24 hr
Clotting time, Lee-White, 37° C	Whole blood (no anticoagulant)		5-8 min
Differential count (see Bone marrow, Differential count or Leukocyte, Differential count)			
Eosinophil count	Whole blood (EDTA); capillary blood	50-400 cells/µL (mm^3)	50-400 × 10^6 cells/L
Erythrocyte count (RBC count)	Whole blood (EDTA)	×10^6 cells/µL M: 4.3-5.7 F: 3.8-5.1	×10^{12} cells/L 4.3-5.7 3.8-5.1
Erythrocyte sedimentation rate (ESR), Wintrobe			M: 0-15 mm/hr F: 0-20 mm/hr
Ferritin (see Table Appendix-2)			
Fibrin degradation products (agglutination, Thrombo-Wellco test)	Whole blood: special tube containing thrombin and proteolytic inhibitor Urine: 2 mL in special tube (see above)	<10 µg/mL <0.25 µg/mL	<10 mg/L <0.25 mg/L
Fibrinogen	Plasma (Na citrate)	200-400 mg/dL	2.00-4.00 g/L
Glucose-6-phosphate dehydrogenase (G6PD) in erythrocytes	Whole blood (ACD, EDTA, or heparin)	12.1 ± 2.09 U/g Hb (1 SD)	0.78 ± 0.13 MU/mol Hb (1 SD)

TABLE APPENDIX-3 HEMATOLOGY AND COAGULATION—cont'd

TEST	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)	REFERENCE INTERVAL (INTERNATIONAL UNITS)
Haptoglobin (Hp)	Serum; avoid hemolysis	26-85 mg/dL	260-1850 mg/L
Hematocrit (HCT, Hct) Calculated from MCV and RBC (electronic displacement or laser)	Whole blood (EDTA)	M: 39-49% F: 35-45%	0.39-0.49 volume fraction 0.35-0.45 volume fraction
Hemoglobin (Hb)	Whole blood (EDTA) Plasma (heparin, ACD) Urine, fresh, random	M: 13.5-17.5 g/dL F: 12.0-16.0 g/dL <3 mg/dL	2.09-2.71 mmol/L 1.86-2.48 mmol/L <0.47 µmol/L Negative
Hemoglobin electrophoresis	Whole blood (EDTA, citrate, or heparin)	HbA > 95% HbA_2 = 1.5-3.5% HbF < 2%	HbA > 0.95 HbA_2 = 0.015-0.035 HbF < 0.02
International Normalized Ratio (INR) (see Prothrombin time)			
Leukocyte count (WBC count)	Whole blood (EDTA) CSF	4.5-11.0 × 10^3 cells/µL (mm^3) 0.5 mononuclear cells/µL	4.5-11.0 × 10^9 cells/L 0.5 × 10^6 cells/L
Leukocyte	Whole blood (EDTA)	% Cells/µL (mm^3)	Number fraction cells × 10^6/L
Differential count Myelocytes Neutrophils-bands Neutrophils-segmented Lymphocytes Monocytes Eosinophils Basophils		 0 0 3-5 150-400 54-62 3000-5800 23-33 1500-3000 3-7 285-500 1-3 50-250 0-0.75 15-50	 0 0 0.03-0.05 150-400 0.54-0.62 3000-5800 0.23-0.33 1500-3000 0.03-0.07 285-500 0.01-0.03 50-250 0-0.0075 15-50
Leukocyte	CSF	%	Number fraction
Differential count Lymphocytes Monocytes (includes pia-arachnoid mesothelial cells) Neutrophils Histocytes Ependymal cells Eosinophils		 62 ± 34 36 ± 20 2 ± 5	 0.62 ± 0.34 0.36 ± 0.20 0.02 ± 0.05 Rare Rare Rare
Mean corpuscular hemoglobin (MCH)	Whole blood (EDTA)	26-34 pg/cell	0.40-0.53 fmol/cell
Mean corpuscular hemoglobin centration (MCHC)	Whole blood (EDTA)	31-37% Hb/cell or gHb/dL RBC	4.81-5.74 mmol Hb/L RBC
Mean corpuscular volume (MCV)	Whole blood (EDTA)		80-100 fL
Methemoglobin (MetHb)	Whole blood (EDTA, heparin, or ACD)	0.06-0.24 g/dL	9.3-37.2 µmol/L
Plasma volume	Plasma (heparin)	M: 25-43 mL/kg F: 28-45 mL/kg	0.025-0.043 L/kg 0.028-0.045 L/kg
Platelet count (thrombocyte count)	Whole blood (EDTA)	150-450 × 10^3/µL (mm^3)	150-450 × 10^9/L
Prothrombin consumption	Whole blood (no anticoagulant)		>30 sec
Prothrombin time, one-stage International Normalized Ratio (INR) for prothrombin time (PT)	Plasma (Na citrate)	Reference values will vary with the type of thromboplastin Relevant only for patients on warfarin $INR = \left[\frac{\text{Patient PT}}{\text{Normal mean PT}}\right]^{ISI\dagger}$ †ISI = International Sensitivity Index of thromboplastin Therapeutic INR > 2.0	In general: 11-15 sec
RBC count (see Erythrocyte count)			
Red cell volume	Whole blood (heparin)	M: 20-36 mL/kg F: 19-31 mL/kg	M: 0.020-0.036 L/kg F: 0.019-0.031 L/kg
Reticulocyte count	Whole blood (EDTA, heparin, or oxalate)	0.5-1.5% of erythrocytes	0.005-0.015 (number fraction)
Sulfhemoglobin	Whole blood (EDTA, heparin, or EDTA)	≤1.0% of total Hb	<0.010 of total Hb (mass fraction)
Thrombin time	Plasma (citrate)		Variable depending on reagent—instrument used, 17-23 sec
Thromboplastin time, activated (see Activated partial thromboplastin time [APTT])			

TABLE APPENDIX-4 DRUGS: THERAPEUTIC AND TOXIC

DRUG	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)		REFERENCE INTERVAL (INTERNATIONAL UNITS)
Acetaminophen	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	10-30 µg/mL >200 µg/mL	66-199 µmol/L >1324 µmol/L
Amikacin	Serum or plasma (EDTA)	Therapeutic: Peak Trough (severe infection) Toxic: Peak Trough	 25-35 µg/mL 4-8 µg/mL >35 µg/mL >10 µg/mL	 43-60 µmol/L 6.8-13.7 µmol/L >60 µmol/L >17 µmol/L
ε-Aminocaproic acid	Serum or plasma (hep or EDTA); trough	Therapeutic:	100-400 µg/mL	0.76-3.05 mmol/L
Amitriptyline	Serum or plasma (hep or EDTA); trough (>12 hr after dose)	Therapeutic: Toxic:	120-250 ng/mL >500 ng/mL	433-903 nmol/L >1805 nmol/L
Amobarbital	Serum	Therapeutic: Toxic:	1-5 µg/mL >10 µg/mL	4-22 µmol/L >44 µmol/L
Amphetamine	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	20-30 ng/mL >200 ng/mL	148-222 nmol/L >1480 nmol/L
Bromide	Serum	Toxic:	>1250 µg/mL	>15.6 mmol/L
Caffeine	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	3-15 µg/mL >50 µg/mL	15-77 µmol/L >258 µmol/L
Carbamazepine	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	4-12 µg/mL >15 µg/mL	17-51 µmol/L >63 µmol/L
Carbenicillin	Serum or plasma	Therapeutic: Toxic:	Dependent on minimum inhibitory concentration of specific organism >250 µg/mL	Same >660 µmol/L
Chloramphenicol	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	10-25 µg/L >25 µg/mL	31-77 µmol/L >77 µmol/L
Chlordiazepoxide	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	400-3000 ng/mL >3500 ng/mL	1.3-10 µmol/L >11.7 µmol/L
Chlorpromazine	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	50-300 ng/mL >1000 ng/mL	157-942 nmol/L >3140 nmol/L
Cimetidine	Serum or plasma (hep or EDTA); trough	Therapeutic:	0.78-3.9 µg/mL	3.1-15.5 µmol/L
Clonazepam	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	20-80 ng/mL >80 ng/mL	63-254 nmol/L >254 nmol/L
Clonidine	Serum or plasma (hep or EDTA)	Therapeutic:	1.0-2.0 ng/mL	4.4-8.7 nmol/L
Clorazepate	Serum or plasma (hep or EDTA)	As desmethyldiazepam: Therapeutic:	 0.12-1.0 µg/mL	 0.36-3.01 µmol/L
Cocaine	Serum or plasma (hep or EDTA) on ice	Therapeutic: Toxic:	100-500 ng/mL >1000 ng/mL	330-1650 nmol/L >3300 nmol/L
Codeine	Serum	Therapeutic: Toxic:	10-100 ng/mL >200 ng/mL	33-334 nmol/L >668 nmol/L
Cyclosporine	Serum (12 hr after dose)	Therapeutic: Toxic:	100-400 ng/mL >400 ng/mL	83-333 nmol/L >333 nmol/L
Desipramine	Serum or plasma (hep or EDTA); trough (≥12 hr after dose)	Therapeutic: Toxic:	75-300 ng/mL >400 ng/mL	281-1125 nmol/L >1500 nmol/L
Diazepam	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	200-1500 ng/mL >3000 ng/mL	0.70-5.27 µmol/L >10.53 µmol/L
Digitoxin	Serum or plasma (hep or EDTA) ≥6 hr after dose	Therapeutic: Toxic:	10-30 ng/mL >45 ng/mL	13-39 nmol/L >59 nmol/L
Digoxin	Serum or plasma (hep or EDTA) trough (≥12 hr after dose)	Therapeutic: CHF Arrhythmias: Toxic:	0.8-1.5 mg/mL 1.5-2.0. ng/mL >2.5 ng/mL	1.0-1.9 nmol/L 1.9-2.6 nmol/L >3.2 nmol/L
Diphenylhydantoin (see Phenytoin)				
Disopyramide	Serum or plasma (hep or EDTA); trough	Therapeutic: Arrhythmias: Atrial Ventricular Toxic:	 2.8-3.2 µg/mL 3.3-7.5 µg/mL >7 µg/mL	 8.3-9.4 µmol/L 9.7-22 µmol/L >20.7 µmol/L
Doxepin	Serum or plasma (hep or EDTA); trough (≥12 hr after dose)	Therapeutic: Toxic:	30-150 ng/mL >500 ng/mL	107-537 nmol/L >1790 nmol/L

TABLE APPENDIX-4 DRUGS: THERAPEUTIC AND TOXIC—cont'd

DRUG	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)		REFERENCE INTERVAL (INTERNATIONAL UNITS)
Ephedrine	Serum	Therapeutic: Toxic:	0.05-0.10 µg/mL >2 µg/mL	0.30-0.61 µmol/L >12.1 µmol/L
Ethchlorvynol	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	2-8 µg/mL >20 µg/mL	14-55 µmol/L >138 µmol/L
Ethosuximide	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	40-100 µg/mL >150 µg/mL	283-708 µmol/L >1062 µmol/L
Fenoprofen	Plasma (EDTA)	Therapeutic:	20-65 µg/mL	82-268 µmol/L
Fentanyl	Serum, plasma	Therapeutic: Toxic:	1-3 ng/mL >3 ng/mL	3-9.2 nmol/L >9.2 nmol/mL
Flecainide	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	0.2-1.0 µg/mL >1.0 µg/mL	0.5-2.4 µmol/L >2.4 µmol/L
Flurazepam	Serum or plasma (EDTA)	Therapeutic: Toxic:	0.02-0.1 µg/mL >0.2 µg/mL	0.05-0.26 µmol/L
Furosemide	Serum (30 min after dose)	Therapeutic:	1-2 µg/mL	3-6 µmol/L
Gentamicin	Serum or plasma (EDTA)	Therapeutic: Peak (severe infection) Trough (severe infection) Toxic: Peak Trough	 8-10 µg/mL <2-4 µg/mL >10 µg/mL >4 µg/mL	 16.7-20.9 µmol/L <4.2-8.4 µmol/L >21 µmol/L >8.4 µmol/L
Glutethimide	Serum	Therapeutic: Toxic:	0.2-5 µg/mL >10 µg/mL	0.92-23 µmol/L >46 µmol/L
Haloperidol	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	5-15 ng/mL >50 ng/mL	13.3-39.9 nmol/L >133 nmol/L
Ibuprofen	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	10-50 µg/mL 100-700 µg/mL	49-243 µmol/L 485-3395 µmol/L
Imipramine	Serum or plasma (hep or EDTA); trough (≥12 hr after dose)	Therapeutic: Toxic:	125-250 ng/mL >500 ng/mL	446-893 nmol/L >1784 nmol/L
Isoniazid	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	1-7 µg/mL >20 µg/mL	7-51 µmol/L >146 µmol/L
Kanamycin	Serum or plasma (EDTA)	Therapeutic: Peak Trough (severe infection) Toxic: Peak Trough	 25-35 µg/mL 4-8 µg/mL >35 µg/mL >10 µg/mL	 52-72 µmol/L 8-16 µmol/L >72 µmol/L >21 µmol/L
Lidocaine	Serum or plasma (hep or EDTA); ≥45 min following bolus dose	Therapeutic: Toxic: CNS or cardiovascular depression Seizures, obtundation, decreased cardiac output	1.5-6.0 µg/mL 6-8 µg/mL >8 µg/mL	6.4-26 µmol/L 26-34.2 µmol/L >34.2 µmol/L
Lithium	Serum or plasma (hep or EDTA); (>12 hr after last dose)	Therapeutic: Toxic:	0.6-1.2 mEq/L >1.5 mEq/L	0.6-1.2 nmol/L >1.5 mmol/L
Lorazepam	Serum or plasma (hep or EDTA)	Therapeutic:	50-240 ng/mL	156-746 nmol/L
Meperidine	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	70-500 ng/mL >1 µg/mL	283-2020 nmol/L >4043 nmol/L
Meprobamate	Serum	Therapeutic: Toxic:	5-10 µg/mL >10 µg/mL	23-46 µmol/L >46 µmol/L
Methadone	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	100-400 ng/mL >2000 ng/mL	0.32-1.29 µmol/L >6.46 µmol/L
Methamphetamine	Serum	Therapeutic: Toxic:	0.01-0.05 µg/mL >0.5 µg/mL	0.07-0.34 µmol/L >3.35 µmol/L
Methaqualone	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	1-3 µg/mL >3-5 µg/mL	4-12 µmol/L >12-20 µmol/L
Methotrexate	Serum or plasma (hep or EDTA)	Therapeutic: Toxic: Low-dose therapy (1-2 wk) High-dose therapy (48 hr)	variable >9.1 ng/mL >227 ng/mL	variable >20 nmol/L >0.5 µmol/L
Methsuximide (*N*-desmethyl methsuximide)	Serum	Therapeutic: Toxic:	10-40 µg/mL >40 µg/mL	53-212 µmol/L >212 µmol/L

TABLE APPENDIX-4 DRUGS: THERAPEUTIC AND TOXIC—cont'd

DRUG	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)		REFERENCE INTERVAL (INTERNATIONAL UNITS)
Methyldopa	Plasma (EDTA)	Therapeutic: Toxic:	1-5 µg/mL >7 µg/mL	4.7-23.7 µmol/L >33 µmol/L
Methyprylon	Serum	Therapeutic: Toxic:	8-10 µg/mL >50 µg/mL	43-55 µmol/L >273 µmol/L
Morphine	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	10-80 ng/mL >200 ng/mL	35-280 nmol/L >700 nmol/L
N-Acetylprocainamide	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	5-30 µg/mL >40 µg/mL	18-108 µmol/L >144 µmol/L
Netilmicin	Serum or plasma (EDTA)	Therapeutic: Peak (severe infection) Trough (severe infection) Toxic: Peak Trough	 8-10 µg/mL <4 µg/mL >12 µg/mL >4 µg/mL	 17-21 µmol/L <8 µmol/L >25 µmol/L >8 µmol/L
Nortriptyline	Serum or plasma (hep or EDTA); trough (≥12 hr after dose)	Therapeutic: Toxic:	50-150 ng/mL >500 ng/mL	190-570 nmol/L >1900 nmol/L
Oxazepam	Serum or plasma (hep or EDTA)	Therapeutic:	0.2-1.4 µg/mL	0.70-4.9 µmol/L
Oxycodone	Serum	Therapeutic: Toxic:	10-100 ng/mL >200 ng/mL	32-317 nmol/L >634 nmol/L
Pentazocine	Serum or plasma (EDTA) Urine	Therapeutic: Toxic: Toxic:	0.05-0.2 µg/mL >1 µg/mL >3 µg/mL	0.2-0.7 µmol/L >3.5 µmol/L >10.5 µmol/L
Pentobarbital	Serum or plasma (hep or EDTA); trough	Therapeutic, hypnotic: Therapeutic coma: Toxic:	1-5 µg/mL 20-50 µg/mL >10 µg/mL	4-22 µmol/L 88-221 µmol/L >44 µmol/L
Phenacetin	Plasma (EDTA)	Therapeutic: Toxic:	5-20 µg/mL >50 µg/mL	28-112 µmol/L >279 µmol/L
Phenobarbital	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic: Slowness, ataxia, nystagmus Coma with reflexes Coma without reflexes	15-40 µg/mL 35-80 µg/mL 65-117 µg/mL >100 µg/mL	65-170 µmol/L 151-345 µmol/L 280-504 µmol/L >430 µmol/L
Phensuximide (both parent and *N*-desmethyl metabolites)	Serum or plasma (hep or EDTA)	Therapeutic:	40-60 µg/mL	228-324 µmol/L
Phenylbutazone	Plasma (EDTA)	Therapeutic: not well defined Toxic:	50-100 µg/mL >100 µg/mL	162-324 µmol/L >324 µmol/mL
Phenytoin	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	10-20 µg/mL >20 µg/mL	40-79 µmol/L >79 µmol/L
Primidone	Serum or plasma (hep or EDTA) trough	Therapeutic: Toxic:	5-12 µg/mL >15 µg/mL	23-55 µmol/L >69 µmol/L
Procainamide	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic: Also consider effect of metabolite, *N*-acetylprocainamide	4-10 µg/mL >10-12 µg/mL	17-42 µmol/L >42-51 µmol/L
Propoxyphene	Plasma (EDTA)	Therapeutic: Toxic:	0.1-0.4 µg/mL >0.5 µg/mL	0.3-1.2 µmol/L >1.5 µmol/L
Propranolol	Serum or plasma (hep or EDTA); trough	Therapeutic:	50-100 ng/mL	193-386 nmol/L
Protriptyline	Serum or plasma (hep or EDTA); trough (≥12 hr after dose)	Therapeutic: Toxic:	70-250 ng/mL >500 ng/mL	266-950 nmol/L >1900 nmol/L
Quinidine	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	2-5 µg/mL >6 µg/mL	6-15 µmol/L >18 µmol/L
Ranitidine	Serum, plasma (hep or EDTA)	Therapeutic:	34-94 ng/mL	114-299 nmol/L
Salicylates	Serum or plasma (hep or EDTA); trough	Therapeutic: Toxic:	150-300 µg/mL >300 µg/mL	1086-2172 µmol/L >2172 µmol/L
Secobarbital	Serum	Therapeutic: Toxic:	1.5-5.0 µg/mL >7 µg/mL	6.3-21.0 µmol/L >29.4 µmol/L
Theophylline	Serum or plasma (hep or EDTA)	Therapeutic: Toxic:	8-20 µg/mL >20 µg/mL	44-111 µmol/L >110 µmol/L

TABLE APPENDIX-4 DRUGS: THERAPEUTIC AND TOXIC—cont'd

DRUG	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)		REFERENCE INTERVAL (INTERNATIONAL UNITS)
Thiocyanate	Serum or plasma (EDTA)	Nonsmoker:	1-4 µg/mL	17-69 µmol/L
		Smoker:	3-12 µg/mL	52-206 µmol/L
		Therapeutic, after nitroprusside infusion:	6-29 µg/mL	103-499 µmol/L
	Urine	Nonsmoker:	1-4 mg/day	17-69 µmol/L
		Smoker:	7-17 mg/day	120-292 µmol/L
Thiopental	Serum or plasma (hep or EDTA); trough	Hypnotic:	1-5 µg/mL	4.1-20.7 µmol/L
		Coma:	30-100 µg/mL	124-413 µmol/L
		Anesthesia:	7-130 µg/mL	29-536 µmol/L
		Toxic conc:	>10 µg/mL	>41 µmol/L
Thioridazine	Serum or plasma (hep or EDTA)	Therapeutic:	0.1-2 µg/mL	0.27-5.4 µmol/L
		Toxic:	>2.5 µg/mL	>6.75 µmol/L
Tobramycin	Serum or plasma (hep or EDTA)	Therapeutic:		
		Peak (severe infection)	8-10 µg/mL	17-21 µmol/L
		Trough (severe infection)	<4 µg/mL	<9 µmol/L
		Toxic:		
		Peak	>10 µg/mL	>21 µmol/L
		Trough	>4 µg/mL	>9 µmol/L
Tocainide	Serum or plasma (hep or EDTA)	Therapeutic:	4-10 µg/mL	21-52 µmol/L
Tolbutamide	Serum	Therapeutic:	50-100 µg/mL	185-370 µmol/L
		Toxic:	>400 µg/mL	>1480 µmol/L
Valproic acid	Serum or plasma (hep or EDTA); trough	Therapeutic:	50-100 µg/mL	347-693 µmol/L
		Toxic:	>100 µg/mL	>693 µmol/L
Vancomycin	Serum or plasma (hep or EDTA); trough	Therapeutic:	5-10 µg/mL	3-7 µmol/L
		Toxic: not well established	>80-100 µg/mL	>55-69 µmol/L
Verapamil	Serum or plasma (hep or EDTA)	Therapeutic:	100-500 ng/mL	220-1100 nmol/L
Warfarin	Serum or plasma (hep or EDTA)	Therapeutic:	1-10 µg/mL	3-32 µmol/L
